The climatic warming in the 1920s (Fig. 13.14) resulted in far greater changes in the distribution and abundance of cod at Greenland than Iceland. Until the 1920s, cod occurred in scattered numbers in inshore waters near Cape Farewell, the southernmost promontory of Greenland (Jensen, 1926, 1939; Tåning, 1948). In the 1920s, cod appeared over wider areas and in increasing numbers. This is shown in the rapid rise in the international catch of cod at West Greenland in the late 1920s, which coincides with the time needed for the 1922 and 1924 year classes to grow to marketable size. Furthermore, cod extended their distribution northward along the west coast of Greenland by 600 to 800 nm in the 1920s and 1930s (Tåning, 1948). At East Greenland, cod appeared in small schools in the Ammassalik area around 1920 and became common around 1930 along the east coast south from Ammassalik (Schmidt, 1931). The drift of 0-group cod from Iceland to Greenland continued on and off from the 1930s to the mid-1960s, although on a smaller scale than for the superabundant year classes of 1922, 1924, and 1945 (Schopka, 1994).

By the early 1930s, West Greenland waters were warm enough for successful spawning of cod (Buch et al., 1994; Hansen, 1949; Hansen et al., 1935; Jensen, 1939; Tåning, 1937). Some members of the 1922 and 1924 year classes took advantage of this, spawned off West Greenland and, with the small inshore cod population, were instrumental in giving rise to a local self-sustaining component. The West Greenland cod stock became very large and sustained annual catches of 300 000 to 470 000 t throughout the 1950s and 1960s. From 1973 to 1993 the average annual catch off West Greenland was about 55 000 t. Peak catches in this period are associated with year classes which drifted as 0-group from Iceland to Greenland. At present, there are few cod at East and West Greenland and no local recruitment to the cod stock (Buch et al., 1994, 2002).

Although fishing mortalities at Greenland increased in the 1950s and 1960s and accelerated the crash of the Greenland cod in the 1970s, the spawning stock remained above 500 000 t until 1970 and produced large year

fate. The spring-spawning stock still shows no sign of recovery, while the summer-spawning stock recovered a few years after a fishing ban was imposed in the early 1970s (Jakobsson and Stefánsson 1999). It seems that, like the West Greenland cod, the Icelandic spring-spawning herring had difficulties in self propagation in cold periods and would probably have collapsed in the late 1960s and early 1970s, even without a fishery (Jakobsson, 1980). The summer-spawning herring, on the other hand, have adapted much better to variability in Icelandic waters. For all three stocks it can be concluded that environmental adversities placed them under reproductive stress and disrupted feeding and migration patterns. Environmental stress, coupled with far too high fishing pressure on both adults and juveniles, resulted in the actual collapses of these herring populations.

While the growth rate of Icelandic capelin has shown a significant positive correlation with temperature and salinity variations in the north Icelandic area since the mid-1970s, this relationship probably describes feeding conditions in the Iceland Sea rather than a direct effect of temperature (Astthorsson and Vilhjálmsson, 2002; Vilhjálmsson, 1994, 2002). Results of attempts to relate recruitment of the Icelandic capelin stock to physical and biological variables, such as temperature, salinity, and zooplankton abundance, have been ambiguous. Nevertheless, judging by their stock size, the Icelandic capelin, which spawn in shallow waters off the south and west coasts of Iceland, seem to have been successful in recent decades and probably also in most years during the latter half of the 20th century.

However, at the peak of warming in the late 1920s and the first half of the 1930s, it was noted that capelin had ceased to spawn on the traditional grounds off the south and west coasts of Iceland and spawned instead off the easternmost part of the south coast as well as in fjords and inlets on the southeast and north coasts (Sæmundsson, 1934). Sæmundsson also noted that the cod had become unusually lean and attributed this to lower capelin abundance. Although there can be other causes of reduced growth of cod, e.g., competition due to a

classes until 1964. Like at Iceland, there was a severe cooling of the Greenlandic marine environment in the latter half of the 1960s and since then the only year classes of commercial significance at Greenland are those of 1973 and 1984, both of which drifted to Greenland as 0-group from Iceland. Despite warmer Greenlandic waters after the cooling of the late 1960s, no year classes of Greenlandic origin have appeared (Vilhjálmsson and Friðgeirsson, 1976; Vilhjálmsson and Magnússon, 1984; Schopka, 1994). This indicates that cod cannot reproduce efficiently at Greenland except under hydrographic conditions that are warmer than "normal".

The fishable part of the Icelandic cod stock (age 4+) declined from almost 2.5 million t in the early 1950s to below 600000 t in 1986. The spawning stock decreased from about 1260 to below 200000 t over this period. The initial large stock size was due to low fishing pressure in and immediately after the Second World War and to the recruitment of the superabundant 1945 year class. A large part of this year class drifted across to Greenland as 0-group and grew in Greenlandic waters. Later, around 500 million members of this year class migrated back to Iceland for spawning and appear not to have left (Schopka, 1994). Despite the cold period of 1965 to 1971 and warmer but more variable conditions since then, recruitment remained at a normal level until 1985, with occasional boosts by immigrants from Greenland, although on a much smaller scale than in 1922, 1924, and 1945 (Schopka, 1994).

Compared to other cod stocks in arctic/subarctic areas, recruitment variability of cod which grow within the Icelandic ecosystem is low or about 1:4 in the period 1920 to 1984. Although it seems that the Icelandic ecosystem cannot support juvenile year classes much beyond sizes corresponding to 300 million recruits at age 3, it has easily accommodated very large numbers of adult cod migrating back from Greenland to their natal spawning grounds. Even the very cold period from 1965 to 1971, and the variable conditions since then, do not appear to have had much detrimental effect on recruitment to the cod stock by fish that grew locally. Average recruitment during 1920 to 1985 was 210 million age 3 cod per annum.

However, since 1985 there has been a large and protracted decline in recruitment, from 210 million to about 135 million age 3 cod per annum. A very small and young spawning stock in the range of 120000 to 210000 t is the only common denominator over this period. This is very likely to have resulted in lower quality eggs, shorter spawning time, smaller spawning grounds, and possibly different drift routes, and seems to be the most plausible explanation for the reduced recruitment (Marteinsdottir and Begg, 2002; Marteinsdottir and Steinarsson, 1998). The most likely explanation for the large year classes of 1983 and 1984, which derived from small spawning stocks, is that old fish from the abundant year classes of 1970 and 1973 were still present in the spawning stock in sufficient numbers to enhance recruitment.

large stock size, Sæmundsson's conclusion may have been correct. The change in capelin spawning areas he described is probably disadvantageous for this capelin stock. The reason being that suitable spawning areas would be much reduced compared to those previously and presently occupied by the stock. Furthermore, larval drift routes could be quite different and a proportion of the larvae would probably end up in the western Norwegian Sea and be spread to regions where their survival rate might be much lower.

The catch history and series of stock assessments of northern shrimp in deep waters northwest, north, and east of Iceland, as well as at Greenland are too short for establishing links with environmental variability. Being a frequent item in the diet of small and medium-sized cod, stocks of northern shrimp are likely to be larger when cod abundance is low. However, in general terms, the stock probably benefits from cooler sea temperatures, possibly through both enhanced recruitment and a reduced overlap of shrimp and cod distribution.

13.3.4. Possible impacts of climate change on fish stocks

To project the effects of climate change on marine ecosystems is a very difficult task, despite knowing the effects of previous climatic change. Previous sections described how the marine climate around Iceland changed over the 20th century, from a cold to a warm state in the 1920s, lasting with some deviations for about 45 years, with a sudden cooling in 1965 which lasted until 1971. Since then, conditions have been warmer but variable and temperatures have not risen to the 1925 to 1964 levels. Available evidence suggests that, as a general rule, primary and secondary production and thereby the carrying capacity of the Icelandic marine ecosystem is enhanced in warm periods, while lower temperatures have the reverse effect. Within limits, this is a reasonable assumption since the northern and eastern parts of the Icelandic marine ecosystem border the Polar Front, which may be located close to the coast in cold years but occurs far offshore in warm periods when levels of biological production are enhanced through nutrient

renewal and associated mixing processes, resulting from an increased flow of Atlantic water onto the north and east Icelandic plateau.

Over the last few years the salinity and temperature levels of Atlantic water off south and west Iceland have increased and approached those of the pre-1965 period. At the same time, there have been indications of increased flow of Atlantic water onto the mixed water areas over the shelf north and east of Iceland in spring and, in particular, in late summer and autumn. This may be the start of a period of increased presence of Atlantic water, resulting in higher temperatures and increased vertical mixing over the north Icelandic plateau, but the time series is still too short to enable firm conclusions.

However, there are many other parameters which can affect how an ecosystem and its components, especially those at the upper trophic levels, will react to changes in temperature, salinity, and levels of primary and secondary production. Two of the most important are stock sizes and fisheries, which are themselves connected. Owing to high fishing pressure since the early 1970s, most of the important commercial fish stocks in Icelandic waters are smaller than they used to be, and much smaller than at the onset of the warming period in the 1920s. Associated with this are changes in age and size distributions of spawning stocks; spawners are now fewer, younger, and smaller. These changes can affect reproductive success through decreased spawning areas and duration of spawning, smaller eggs of lower quality, and changes in larval drift routes and survival rates (Marteinsdottir and Begg, 2002; Marteinsdottir and Steinarsson, 1998). It is unlikely that the response of commercial fish stocks to a warming of the marine environment at Iceland, similar to that of the 1920s and 1930s, will be the same in scope, magnitude, and speed as occurred then. Nevertheless, a moderate warming is likely to improve survival of larvae and juveniles of most species and thereby contribute to increased abundance of commercial stocks in general. The magnitude of these changes will, however, be no less dependent on the success of future fishing policies in enlarging stock sizes in general and spawning stock biomasses in particular, since the carrying capacity of Icelandic waters is probably about two to three times greater than that needed by the biomass of commercial species in the area at present.

The following sections describe three possible scenarios of warming for the marine ecosystems of Iceland and Greenland and attempt to project the associated biological and socio-economic changes.

13.3.4.1. No climate change

Although the marine climate may dictate year-class success in some instances, there is little if any evidence to suggest that year-class failure and thereby stock propagation is primarily due to climate-related factors. Therefore, assuming no change from the ACIA baseline climate conditions of 1981–2000, the development and

potential yield in biomass of commercial stocks will in most cases depend on effective rational management, i.e., a management policy aimed at increasing the abundance of stocks through reduced fishing mortalities and protection of juveniles. This is the present Icelandic policy. Although it has not yet resulted in much tangible success, it should eventually do so and with a speed that largely depends on how well incoming year classes of better than average size can be protected from being fished as adolescents.

A successful fishing policy of this kind should ensure an increase in the abundance of many demersal fish stocks by around 2030. This would considerably increase the sustainable yield from these stocks compared to the present. This could also apply for the Icelandic summer-spawning herring, although that stock is already exceeding its historical maximum abundance. The increase in yield in tonnes is, however, not directly proportional to increase in stock abundance. Thus, a doubling of the fishable biomass of the Icelandic cod stock would probably increase its long-term sustainable yield in tonnes by about 20 to 30% compared to the present annual catch of about 200 000 t. Furthermore, due to natural variability in the size of recruiting year classes, increases in stock biomasses of the various species are most likely to occur in a stepwise fashion and the value of the catch would not necessarily increase proportionally.

However, on the negative side, it is likely that the northern shrimp catch would decrease due to increased predation by cod and that the capelin summer/autumn fishery would have to be reduced or stopped altogether, in order for the needs of their more valuable fish predators to be met and those of large whales, if whales remain subject to a moratorium on commercial whaling. Increases in abundance, but especially extended migrations of the Norwegian spring-spawning herring to feed in north Icelandic waters, will determine the value of the yield from that stock for Iceland. For this to occur on a long-term basis, the intensity of the cold East Icelandic Current must weaken and temperatures north of Iceland must increase. Such conditions are not envisaged under this scenario.

At Greenland, the no-change scenario will have little effect on the present situation, given that stocks are presently managed in a rational manner and that this is expected to continue.

13.3.4.2. Moderate warming

Most criteria in the no-change scenario are probably also valid for a moderate warming of 1 to 3 ºC. However, due to greater primary and secondary production and a direct temperature effect *per se*, stock-rebuilding processes are likely to be accelerated in most cases. Nevertheless, as for the no-change scenario, a rational fishing policy must be maintained. Indeed, it is very likely that harvesting strategies can be used which would give higher returns from most of the major dem-

ersal stocks in the Icelandic area. As under the no-change scenario, a side effect of such a policy would be a rise in the mean age and number of older fish in the spawning stock of cod, which would further enhance larval production and survival.

Drift of larval and 0-group cod across the northern Irminger Sea to East Greenland and onward to West Greenland waters is likely to become more frequent and the number of individuals transported to increase compared to the latter half of the 20th century. Since sea temperature off West Greenland will also increase under this scenario, it is very likely that the drift of cod larvae and juveniles from Iceland will lead to the establishment of a self-sustaining Greenlandic cod stock. With a successful management strategy and in the light of past events, that cod stock could become very large and have enormous positive economic benefits for Greenland (see section 13.3.6.2). However, it is unlikely that this will contribute much to cod abundance at Iceland. This is because present fish finding and catch technologies are so effective that these cod can, and very likely will, be easily fished in Greenlandic waters before they could return to Iceland for spawning at the age of seven to eight years.

An increase in temperature of 1 to 3 °C in the north Icelandic area is large in comparative terms and will, among other things, be associated with a weakening of the East Icelandic Current and a considerable reduction in its domain. The degree of reduction is very likely to be sufficient to enable the Norwegian spring-spawning stock to again take advantage of the rich supply of *Calanus finmarchicus* over the north Icelandic shelf. This scenario would make it easier and cheaper for Iceland to take its share of this stock, and would also make the stock more valuable. The reason for this is a large increase in the proportion of the catch which could be processed for human consumption compared to the current situation where a large proportion must be reduced to the comparatively cheaper fishmeal and oil. It is also very likely that more southern species such as mackerel and tuna will enter Icelandic waters in sufficient concentrations for commercial fishing in late summer and autumn.

13.3.4.3. Considerable warming

According to the B2 emissions scenario, model results indicate that a rise in temperature beyond 2 to 3 °C in the Icelandic area in the 21st century is unlikely. However, should that happen, the high temperature is likely to lead to dramatic changes to the Icelandic marine ecosystem. Section 13.3.1 described the key role of capelin for the well-being of many demersal stocks, and highlighted the large reduction in weight-at-age of Icelandic cod during the two capelin stock collapses. Capelin spawning also ceased on their traditional grounds off the south and west coasts of Iceland in the late 1920s and early 1930s, occurring instead in fjords and inlets on the southeast and north coasts (Sæmunds-

son, 1934). Under such conditions the extent of capelin spawning grounds would reduce considerably. Should the rise in sea temperature increase beyond that of the 1920 to 1940 period, it is likely that capelin spawning might be even further reduced and limited to the north and east coasts of Iceland. This would result in major changes in larval drift routes and survival and, eventually, to a large reduction in, or even a complete collapse of, the Icelandic capelin stock.

Owing to the key role of capelin as forage fish in the Icelandic marine ecosystem this scenario would be very likely to have a considerable negative impact on most commercial stocks of fish, whales, and seabirds which are dominant in this ecosystem at present. Such a scenario is also very likely to result in species from more temperate areas moving into the area and at least partially replacing those most affected by a lack of capelin.

13.3.5. The economic and social importance of fisheries

### 13.3.5.1. The fishing industry and past economic fluctuations

Iceland

During the 20th century, the Icelandic gross domestic product (GDP) had an average annual growth of about 4% per year. This was largely driven by expansion in the fisheries and fish processing industries. Furthermore, fluctuations in aggregate economic output were highly correlated with variations in the fishing industry. Good catches and high export prices resulted in economic growth, while poor catches and adverse foreign market conditions led to economic slowdown and even depression. All five major economic depressions in the 20th century can be directly related to changes in the fortunes of the fishing sector, either wholly or partially (Agnarsson and Arnason, 2003).

The first of these major depressions covers the period of the First World War, which had catastrophic effects on Iceland, as it did on many other European countries. The first two years of the war were favorable for the fishing sector however, as increased demand pushed up foreign prices, but in 1916 the international trade structure broke down and Iceland had to accept harsh terms of trade with the Allies. In 1917, Iceland was forced to sell half its trawler fleet to France. This led to substantially reduced demersal fish and herring catches in 1917 and 1918. The result was a sharp drop in GDP and a depressed economy until 1920 (Fig. 13.17).

The effects of the "Great Depression" were first felt in Iceland in autumn 1930, and in the following two years GDP fell by 0.5% and 5% respectively as demand for maritime exports declined sharply. Following a brief recovery, the economy was hit again when the Spanish Civil War broke out in 1936 and closed Iceland's most important market for fish products. Despite these
Fig. 13.17. GDP growth in Iceland, 1901–2000: showing major depressions (Agnarsson and Arnason, 2003).

events, economic growth still averaged 3% in the 1930s, mostly because of strong rebound in the fisheries, especially the herring fisheries, in 1933 to 1939. The strong performance of the fisheries in the 1930s appears to be the reason that the "Great Depression" was felt less in Iceland than most other countries of Western Europe.

The Second World War was a boom period for Iceland led by good catches and very favorable export prices. But in 1947 and subsequent years, herring catches fell considerably and real export prices subsided from the high wartime levels. The result was a prolonged economic recession from 1949 to 1952.

During the 1960s, the economy grew at an average rate of 4.8%. This was largely due to very good herring fisheries. When the herring stocks collapsed toward the end of the decade the result was a severe economic depression in 1968 and 1969, when the GDP declined by 1.3% and 5.5% respectively. Unemployment reached over 2% – a great shock for an economy used to excess demand for labor since the 1930s – and many households moved abroad in search of jobs. Net emigration amounted to 0.6% of the total population in 1969 and 0.8% in 1970.

High economic growth resumed between 1971 and 1980 with annual rates averaging 6.4%. However, just as during the 1960s, this growth was to a significant extent based on overexploitation of the most important fish stocks. Reduced fishing quotas and weak export prices reduced fishing profitability in the late 1980s. And, partly as a consequence of this, the Icelandic economy was stagnant between 1988 and 1993, with an average annual decline in GDP of 0.12%.

Since 1993, the Icelandic economy has shown steady and impressive annual growth rates. One reason for this is a recovery of some fish stocks. More important, however, are more favorable fish export prices and the impact of the individual transferable quota (ITQ) system. The ITQ system has enabled the fishing industry to increase and stabilize profits and more easily adjust to changing quotas and fish availability.

Thus, over the 20th century as a whole, it appears that major fluctuations in the Icelandic economy largely reflect changes in the fortunes of the fishing industry both in terms of harvest quantity and output prices. This implies that possible changes in fish stocks due to climate change may have similar macro-economic effects. However, it is very likely the macro-economic impact of any given change in fish availability will be smaller in the future than in the past. First, because the importance of the fishing industry for the Icelandic economy has declined substantially, and second, because the ITQ system has probably made the fishing industry more capable of adapting to changes in fish stocks. However, it must be noted that if the current depressed state of some of the most important fish stocks persists, adverse environmental changes may actually translate into larger biological shocks than those experienced in the past.

Greenland

Greenland does not offer the same overwhelming evidence of the national economic importance of the fishing industry as Iceland. This, however, does not mean that the economic importance of the Greenland fishing industry is any less than in Iceland. In fact it is probably much greater.

First, the Greenland fishing industry developed much later than that in Iceland. Thus, the Greenland fishing activity was relatively insignificant over the first half of the 20th century (see Fig. 13.9) even when compared to the rest of the Greenland economy. Second, being based on underexploited fish stocks, the Greenland fishing industry expanded relatively smoothly until the 1980s, resulting in far fewer of the dramatic fluctuations in fisheries output experienced in Iceland. Third, the Greenland economic statistics are less comprehensive than in Iceland, meaning fewer data.

Since 1970, there have been two major cycles in the Greenland economy (Fig. 13.18) both associated with changes in the fishing industry, more precisely the cod fishery.
Fig. 13.18. GDP growth in Greenland, 1975–1999: showing major depressions (Anon, 2000).

Historically, the cod fishery has been Greenland's most important fishery (although this has now been superceded by the shrimp fishery). The cod fishery underwent a major expansion in the latter half of the 1970s due to reduction in foreign fishing following the extension of the Greenland fisheries jurisdiction to 200 nm and a greatly expanded Greenland fishing effort. This led to a period of good economic growth that reversed abruptly in 1981 with a major contraction of the cod fishery due to a combination of overfishing and low export prices. The subsequent period of economic depression lasted for three years during which the GDP decreased by 9% per year. Another short-lived boom in the cod fishery from about 1985 led to a corresponding boom and bust cycle in the economy with a five-year growth period followed by a sharp depression lasting four years during which GDP decreased by over 20%. Economic growth resumed in Greenland in 1995, not on the basis of cod, which has not reappeared, but shrimp fishing which expanded very rapidly during the latter half of the 1990s.

As in Iceland, historical evidence indicates a close connection between fluctuations in GDP and variations in the Greenland fishing industry.

13.3.5.2. The economic and social role of fisheries

Iceland

The relative importance of the fishing industry in the Icelandic economy seems to have peaked before the middle of the 20th century. Since then, both the share of fish products in merchandise exports and the fraction of the total labor force engaged in fishing have declined significantly. In 2000, the fishing industry employed 8% of the labor force, accounted for 63% of merchandise exports, and generated 42% of export earnings. Total export value of fish products in 2000 was about US$ 1220 million.

National accounts estimates of the contribution of the fishing industry to GDP – available since 1980 – confirm this trend. Thus, in 1980 the direct contribution of the fishing industry to GDP was over 16%. In 2000, this had dropped to just over 11%, which corresponds to an added US$ 900 million.

These aggregate statistics will understate the real contribution of the fishing industry to the Icelandic economy. There are two fundamental reasons for this. The first is that there are a number of economic activities closely linked to the fishing industry but not part of it. These comprise the production of inputs to the fishing industry, the so-called "backward linkages", and the various secondary uses of fish products, the so-called "forward linkages" (Arnason, 1994). The backward linkages include activities such as shipbuilding and maintenance, fishing gear production, the production of fishing industry equipment and machinery, the fish packaging industry, fisheries research, and education. The forward link-

ages comprise the transport of fish products, the production of animal feed from fish products, the marketing of fish products, and retailing of fish products. According to Arnason (1994), these backward and forward linkages may add at least a quarter to the direct GDP contribution of the fishing industry.

The other reason why the national accounts may underestimate the contribution of the fishing industry to GDP is the role of the fishing industry as a disproportionately strong exchange earner. To the extent that the availability of foreign currency constrains economic output, the economic contribution of a disproportionately strong export earner may be greater than is apparent from the national accounts. While the size of this "multiplier effect" is not easy to measure, some studies suggest it may be quite significant (Agnarsson and Arnason, 2003; Arnason, 1994). If this is the case, the total contribution of the fishing industry to GDP may be much higher than estimates suggest, in the sense that removing the fishing industry would, with all other things remaining the same, lead to this reduction in GDP.

There are also economic reasons as to why a change in the conditions of the fishing industry due, for example, to climate change, might have a lesser economic impact than suggested by the direct (and indirect) contribution of the fishing industry to GDP. Most economies exhibit some resilience to exogenous shocks. This means that the initial impact of such shocks is at least partly counteracted by the movement of labor and capital to economic activities made comparatively more productive by the shock. Thus, a negative shock in the fishing industry would to a certain extent be offset by labor and capital moving from the fishing industry to alternative industries and vice versa. Thus, the long-term impact of such a shock may be much less than the initial impact. The extent to which this happens depends on the availability of alternative industries. However, with increased labor mobility, communication technology, and human capital this type of flexibility is probably much greater than in the past.

Regional importance

Analysis in terms of macro-economic aggregates does not take into account that the economic importance of the fishing industry varies from one region of the country to another. In 2000, when the fishing industry (harvesting and processing) employed only about 8% of the

Table 13.1. The importance of the fishing sectors to Icelandic communities in 1997.

Labor share of the fishing sectors (%)	Number of communities	Number of inhabitants	Percentage of total population
>40	24	12812	7.7
25–40	16	23063	8.6
10–25	14	36959	13.7
5–10	16	26832	10.0
<5	54	161922	60.1

national workforce, it provided jobs for over 35% of the working population in the western fjords and almost 30% of the working population in the eastern fjords. Both regions are sparsely populated and account for only a small proportion of the total Icelandic population. Near the capital, Reykjavík, where most of the alternative industries such as manufacturing and services are located, the fishing industry employed only about 3% of the working population.

The local importance of the fishing industry is even more apparent at the community level. In 1997, the fishing industry accounted for over 40% of the local employment in 24 out of a total of 124 municipalities in Iceland (Table 13.1). A typical example of a community totally dependent on fishing is Raufarhofn, a small community of 400 inhabitants in northeast Iceland. Almost 70% of the adult population worked in the fishing industry in 1997. In four other communities the fishing industry accounted for over 60% of total employment in 1997.

By contrast, in 54 communities the fishing industry accounted for less than 5% of total employment. Most of the largest municipalities in Iceland belong to this group. It is mainly the smaller, economically less developed communities that depend heavily on fisheries (see Table 13.1).

Thus, the effects of a significant reduction in fish availability around Iceland, or the benefits of fisheries expansion would be differently felt in the various regions and communities of Iceland. In general terms, a significant reduction in fish availability is liable to be economically and socially disastrous for the western and eastern fjord regions and for certain other smaller regions of Iceland, while in the more densely populated southwest of Iceland such a reduction would be felt mainly as an increased influx of labor from the outlying regions and the corresponding realignment of economic activity.

Although labor mobility is high in Iceland, it may not be easy for inhabitants of fishing villages to find jobs elsewhere following a decline in fisheries due to climate change, especially if the economy is already depressed. Also, as many of the employment opportunities in and around the capital require particular education and training, individuals transferring from the fishing industry may have to accept relatively inferior jobs. At the same time, reduced employment and movement out of the fisheries-dependent regions and communities of Iceland will decrease real estate values in these areas, meaning that these migrants may have to suffer a significant decrease in the value of their assets at the same time as moving to seek new employment.

Thus, a significant reduction in the Icelandic fishing industry would lead to noticeable social disruption. However, given the nature of Icelandic society, it would probably be resolved within five to ten years of the initial shock, although the disruption would impose a certain stress on the social and political system during this period of adjustment.

Greenland

The fishing industry is by far Greenland's most important production sector. In the 1960s and early 1970s fish and fish products accounted for between 80 and 90% of Greenland's total export value. In 1974, there was a very large increase in the export of lead and zinc, which increased GDP by about 50% and caused fish and fish products to fall to between 60 and 70% of total export value. The export of lead and zinc ceased in 1990. Since then, export of fish and fish products has accounted for about 90% of Greenland's total export value. In 2000, the export value of fish and fish products was about US$ 270 million and the total export value about US$ 285 million.

Exact statistics about the direct contribution of the fishing industry to the Greenland GDP are not available. However, the contribution to the gross national income (GNI) may be as high as 20%. This, however, does not tell the complete story. Greenland is part of Denmark with a "Home Rule" government. This means that Greenlanders can decide their own policies, except for foreign and defense policy. Every year, the Home Rule government receives economic support from the Danish State. In 2000 this amounted to about US$ 350 million or almost 25% of GNI. Correcting for this indicates a direct contribution of the fishing industry to the Greenland GDP of 25 to 30%.

As for Iceland, however, the fishing industry also has an indirect contribution to the Greenland economy via forward and backward linkages as well as multiplier effects. Adding these may bring the total contribution of the fishing industry to the Greenland economy as a whole to over 50%.

Regional importance

Greenland as a whole is highly dependent on the fishing industry. This is even more the case in less populated communities along the coast. About 20% of Greenland's population lives in small villages and settlements with an average population of about 150 inhabitants. Many more live in small towns with less than a thousand inhabitants. The economic activity in these communities is almost exclusively based on the exploitation of living marine resources, i.e., through fishing and hunting. Also, the geographical isolation of many of these communities means alternative employment opportunities are few if any.

Thus, a significant drop in the fish stocks and other living marine resources would have a devastating impact on these communities. Most would decrease significantly and many would disappear altogether, causing those inhabitants that left to become economically and socially dispossessed. A secondary effect would be the substantial influx of these people to the more urban areas of Greenland and the problems that this would cause.

A significant increase in the stocks of fish and other living marine resources would cause the reverse effect and would strengthen the economic basis of Greenland's smaller communities. While larger towns may benefit disproportionately from such a change, the net effect would probably be to increase population in the smaller communities and to expand the geographical extent of habitation in Greenland.

13.3.6. Economic and social impacts of climate change: possible scenarios

From an economic point of view, climate change may impact on fisheries in at least two ways: by altering the availability of fish to fishers and by changing the price of fish products and fisheries inputs. Although both types of impact may be initiated by climate change, the former is a more direct consequence of climate change than the latter.

The possible impact of climate change on fish availability may occur through changes in the size of commercial fish stocks, changes in their geographical distribution, and changes in their catchability. These changes, if they occur, will affect the availability of fish for commercial harvesting. The direction of this impact is uncertain. It may be negative, and so reduce the maximum sustainable economic yield from the fish stocks, or positive, and so increase the maximum sustainable economic yield from the fish stocks. Also, the impact may vary for different fish stocks and for different regions. Irrespective of the direction of the impact, however, it is very likely that climate change will, at least temporarily, cause instability or fluctuations in harvesting possibilities while ecosystems adjusts to new conditions. The adjustment period may be long, and may even continue after the period of climate change has ended.

The same applies to changes in economic value in that relative prices may continue to adjust after an exogenous shift, such as climate change, has been resolved. In fact, economic adjustments following climate change, being dependent on biological/ecological adjustments, will by necessity continue after the latter are complete.

This section speculates on the possible economic and social impacts in Iceland and Greenland of changes in fish availability. The possible impacts of relative price changes are not discussed. However, the economic and social impacts of price changes will be similar to those of changes in fish stock availability. In terms of drawing inferences from historical evidence, it is not important whether expansions and contractions in the fishing industry result from changes in prices or fish availability.

Empirical evidence of possible economic impacts of changes in fish stock availability is either qualitative historical evidence or quantitative evidence. Qualitative evidence (discussed in section 13.3.5.1) relates economic fluctuations to qualitative evidence of expansions and contractions in the fishing industry. Quantitative evi-

dence, in the form of time series for fisheries production and production values, provides a basis for statistical estimates of the relationship between the production value of the Icelandic and Greenland fishing industries and their respective GDP and Gross National Product (GNP) growth.

13.3.6.1. Iceland

Reliable time series data for the output and output value of the fishing industry are available since 1963. These data have been used to estimate the form and parameters of a relationship between economic growth rates and the output value of the fishing industry as well as other relevant economic variables such as capital and labor (Agnarsson and Arnason, 2003). The equation exhibits good statistical properties and actual and fitted GDP growth rates are illustrated in Fig. 13.19.

This equation can, with certain modifications, be used to predict the short- and long-term impact of a change in fish stock availability due to climate change. It is important to realize, however, that to use this equation it is necessary to project (1) the extent and timing of climate change, (2) the impact of global climate change on fish stock availability, and (3) the impact of changed fish stock availability on the value of fish production (which involves both the volume and price of fish production).

Impact on GDP

This section presents the outcome of calculations to estimate the possible impact on GDP of changed fish stock availability as a result of climate change. The impact of other variables on the value of fish production is ignored. The calculations are based on two key factors: the impact of future climate change on the value of fish production in Iceland and the estimated relationship between economic growth and the value of fish production (see Agnarsson and Arnason, 2003). Both are highly uncertain. Thus, the following calculations must not be regarded as predictions. They are intended to serve as

Fig. 13.19. GDP growth in Iceland, 1966–1997: actual and fitted values.

indications of the likely magnitudes of the impact on GDP in Iceland resulting from certain stated premises regarding changes in fish stock availability.

Available projections (see section 9.3.4.4) suggest that climate change over the next 50 to 100 years is (1) unlikely to have a great impact on fish stock availability in Icelandic waters and (2) is very likely to benefit the most valuable fish stocks. As a result, the overall effects of climate change on the Icelandic fisheries are likely to be positive. As these expectations are very uncertain, the rest of this section illustrates this point using three scenarios.

The first scenario assumes a gradual increase in fish stock availability of 20% over a period of 50 years. This is known as the "optimistic" scenario and corresponds to a 0.4% increase in the value of fish production annually. The second scenario assumes a gradual reduction in fish stock availability of 10% over 50 years. This is known as the "pessimistic" scenario and corresponds to an annual reduction in the value of fish production by 0.2%. The third scenario assumes a 25% reduction in fish stock availability over a relatively short period of five years. This corresponds to a collapse in the stock size of one major species or a group of important commercial species. In fact, there are some indications that the response of fish stocks to climatic change may be sudden and discontinuous rather than gradual. Owing to the magnitude and suddenness of this reduction it is known as the "dramatic" scenario.

These scenarios illustrate the likely range of economic impacts of climate change around Iceland. In interpreting their outcomes it is important to remember that these scenarios are restricted to the impact of climate change assuming all other variables affecting fish stocks and their economic contribution are unchanged. These outcomes do not incorporate the possibly simultaneous impact of improved fisheries management or other variables affecting the size of fish stocks and the value of the fisheries. In fact, given the currently depressed state of many of the most valuable fish stocks in Iceland, a better harvesting policy may easily contribute at least as much to the overall economic yield of the fisheries as the most optimistic climate scenario. However, such a policy will also improve the outcomes of the more pessimistic climate scenarios.

Optimistic scenario

In the optimistic scenario, fish stock availability is assumed to increase in equal steps by 20% over the next 50 years. The impact of this scenario on GDP relative to a benchmark GDP of unity is illustrated in Fig. 13.20. The figure illustrates that this quite considerable increase in fish stock availability has only a relatively minor impact on GDP. The maximum impact occurs in year 50, when increased fish stock availability has fully materialized. At this point GDP has increased (com-

pared to the initial level) by less than 4%. The long-term impact, after economic adjustment processes are complete, is even less at around 2.5%. The largest annual increase in GDP is small at under 0.2%, and is substantially less than the GDP measurement error. Thus it would be hardly noticeable. In the years following the end of the increase in fish production, growth rates decline as production factors (which move to the fishing industry) reduce economic production elsewhere. Long-term GDP growth rates are, of course, unchanged. The main conclusion to be drawn is that a 20% increase in the output of the fishing industry equally spread over 50 years has a very small, hardly noticeable, impact on the short-term economic growth rates in Iceland as well as on long-term GDP.

Pessimistic scenario

In the pessimistic scenario, fish stock availability is assumed to decrease in equal steps by 10% over the next 50 years. The impact of this scenario on GDP relative to a benchmark GDP of unity is also illustrated in Fig. 13.20. As in the optimistic scenario, it is apparent that this considerable decrease in fish stock availability has a relatively minor impact on long-term GDP. The maximum impact also occurs in year 50, at which point GDP has been reduced by less than 2%. The long-term impact, after economic adjustment processes are complete, is even less or just over 1%. The largest annual decrease in GDP is well over -0.1%. This occurs a few years after the decrease in fish stock availability begins. For most of the period, however, the impact on annual economic growth rates is much less. In the years following the end of the decrease in fish production, growth rates improve, as production factors (which move from the fishing industry) find productive employment elsewhere. All these deviations in annual GDP growth rates are well within GDP measurement errors. Long-term GDP growth rates are, of course, unchanged. As under the optimistic scenario, the main conclusion to be drawn is that a 10% decrease in output from the fishing industry equally spread over 50 years has a negligible impact on the short-term economic growth rates in Iceland as well as on long-term GDP.
Fig. 13.20. Iceland: impact of different scenarios on GDP (benchmark GDP = 1.0).

Dramatic scenario

The dramatic scenario assumes a fairly substantial drop in fish stock availability and, hence, fish production of 25% over the next five years. The impact of the dramatic scenario on GDP relative to a benchmark GDP of unity is illustrated in the lowest curve in Fig. 13.20. This sudden drop in fish stock production has a significant negative impact on GDP in the short term. At its lowest point, in year eight, GDP is reduced by over 9% (compared to the initial level). The long-term negative impact, after economic adjustment processes are complete, is only about a 3% reduction in GDP. The decrease in annual GDP growth rates for the first seven years following the start of reduced fish stock production are significant or -1 to -2%. The maximum decline occurs toward the end of the reduction process in years four and five. However, only four years later, the contraction ends, and the deviation in annual GDP growth rates is reversed as production factors released from the fishing industry find productive employment elsewhere. According to these calculations, this adjustment process is complete by year 25 when growth rates have reverted to the underlying economic growth rate.

Social and political impacts

If the change in fishing industry output is gradual and the economic impact comparatively small (as in the "optimistic" and "pessimistic" scenarios), it is unlikely that the accompanying social and political impacts will be noticeable at a national level. Although over the long term, social and political impacts will undoubtedly occur, whether these will be large enough to be distinguished from the impact of other changes is uncertain. Regionally, however, the situation may be very different. In some parts of Iceland (see section 13.5.2) the economic and social role of the fishing industry is far above the national average. In these areas, the economic, social, and political impact of an expansion or contraction in the fishing industry will be much greater than for Iceland as a whole and in some areas undoubtedly quite dramatic.

If, on the other hand, the change is fairly sudden (as in the "dramatic" scenario) the short-term social and political impact may be quite drastic. In the long term, however, after the initial impact, social and political conditions will revert to the long-term scenario described by the "pessimistic" scenario. Whether the economic and social adjustments will then also revert to their initial state is not clear.

Impacts on fish markets

Reductions or increases in fish production in Iceland alone will not have a significant impact on global fish markets. Neither are they likely to have a large impact on the marketing of Icelandic fish products, provided the changes are gradual. If there is an overall decline in the global supply of species of fish that Iceland currently exploits, the impact on marketing of these species is uncertain. Almost certainly the marketing of the species in reduced supply will become easier. Thus, prices will rise counteracting the decrease in volume. However, the marketing impact might actually be the opposite. For some species, a large and steady supply is required to maintain marketing channels. If this is threatened, these channels may close and alternative outlets will have to be found.

Discussion

The main conclusion to be drawn is that the changes in fish stock availability that seem most likely to be induced by climate change over the next 50 to 100 years are unlikely to have a significant long-term impact on GDP in Iceland and, consequently, on social and political conditions in Iceland. Also, it appears that any impact, small as it may be, is more likely to be positive than negative. However, if on the other hand, climate change results in sudden rather than gradual changes in fish stock availability, the short-term impact on GDP and economic growth rates may be quite significant. The impact seems very unlikely to be dramatic (i.e., over 5% change in GDP between years) however. Over the long term, the impact on GDP of a sudden change in fish stocks will be indistinguishable from the effects of more gradual change. Long-term social and political impacts may differ although there is no clear evidence to support this.

13.3.6.2. Greenland

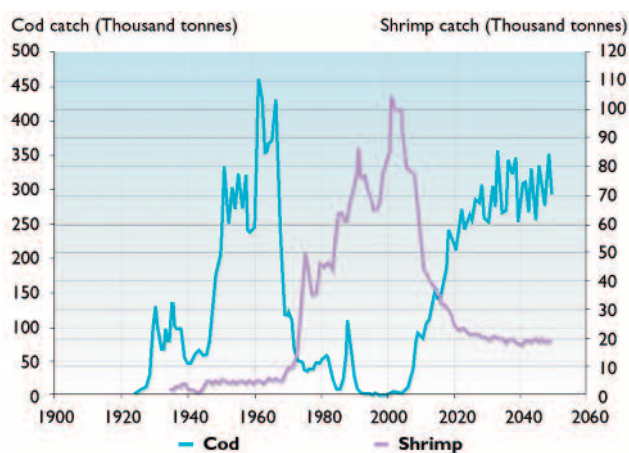
Reliable time series data for the export value of the Greenland fishing industry are available since 1966. These data have been used to estimate the form and parameters of a relationship between GDP and the real export value of fish products (Vestergaard and Arnason, 2004). The equation exhibits reasonable statistical properties. Actual and fitted GDP growth rates according to this equation are illustrated in Fig. 13.21. It is projected that a 1% increase in the export value of fish products will lead to a 0.29% increase in the Greenland GDP. Subject to the same qualifications as for Iceland, this equation can be

**Fig. 13.21.** GDP in Greenland, 1970–1999: actual and fitted values.

used to predict the economic impact of a change in fish stock availability resulting from climate change.

Impact on GDP

Available projections (see section 9.3.4.4 and sections 13.3.3.3, 13.3.3.4, and 13.3.4.1 to 13.3.4.3) suggest that climate change over the next 100 years is very likely to benefit the most valuable fish stocks at Greenland. This is particularly likely to be the case for the cod stock, which could experience a revival from its current extremely depressed state to a level, seen during warm periods of the 20th century, where it could yield up to 300000 t on a sustainable basis. However, climate change and increased predation by cod could lead to a dramatic fall in the sustainable harvest of shrimp by up to 70000 t (Fig. 13.22). The value of the increased cod harvest would, however, greatly exceed losses due to a possibly reduced harvest of shrimp. In fact, this change could lead to doubling or even tripling of the total production value of the Greenland fishing industry. Thus, the projected climate change could have a major positive impact on the Greenland fishing industry. However, this is highly uncertain. As was the case for Iceland this section continues on the basis of three scenarios.

The first scenario, termed the "pessimistic" scenario, assumes that despite more favorable habitat conditions, cod will not reestablish permanently in Greenland waters. Instead, there will be periodic bursts of cod availability accompanied by a corresponding drop in shrimp, based on occasional large-scale larval drift from Iceland similar to that seen in warmer periods in the past. The overall impact will be a slight average increase in fish harvests with some peaks and troughs. The second scenario, termed the "moderate" scenario, assumes a modest and gradual return of cod to Greenland which in 20 years would be capable of yielding 100000 t per year on average. This would be accompanied by a corresponding decline in the shrimp stock. The third scenario, termed the "optimistic" scenario, assumes a return of the Greenland cod stock, initially generated by Icelandic cod larval drift, to the levels of the 1950s


and 1960s. A full revival, however, would take some decades and would occur in a fluctuating manner. Ultimately, in about 30 years, the cod stock would be capable of producing an average yield of 300000 t per year, compared to almost nothing at present. The average shrimp harvest, however, would be reduced from a current level of almost 100000 t per year to about 20000 t per year. Nevertheless, the overall value of the Greenland fish harvest would almost double. These scenarios illustrate the likely range of economic impacts of climate change around Greenland. The harvest projections are all based on a two-species fisheries model developed for the Greenland fisheries (Hvingel, 2003).
Pessimistic scenario

The pessimistic scenario assumes an insubstantial change in overall average fish stock availability. However, due to the occasional large-scale influx and survival of Icelandic cod larvae, periodic bursts in cod availability occur. This situation results in fluctuating fish production rates and GDP impacts over time (see lowest curve in Fig. 13.23) with a small average increase. The average increase in GDP after 50 years is about 2% higher than would otherwise have been the case.

Moderate scenario

In the moderate scenario, fish stock availability is assumed to increase gradually by about 20% over the next 100 years. The impact of this scenario on GDP relative to a benchmark GDP of unity is shown by the middle curve in Fig. 13.23. This increase in the availability of fish leads to a moderate long-term increase in GDP of 6% (compared to the initial level). However, as most of this increase is projected to occur over the first ten years (in fact the initial impact is projected to be greater than the long-term impact) there would be a significant addition to GDP of 1% per year during this initial period.

Optimistic scenario

In the optimistic scenario, fish stock availability is assumed to increase gradually, but in a fluctuating man-

Fig. 13.22. The history and possible future development of cod and shrimp harvests in Greenland under global warming (Hvingel, in prep).

Fig. 13.23. Greenland: impact of different scenarios on GDP (benchmark GDP=1.0).

ner, by about 100% over the next 50 years. The projected relationship between the value of fish exports and GDP suggests that this will lead to an ultimate increase in GDP of 28% compared what would otherwise have been the case. This impact relative to a benchmark GDP of unity is illustrated in Fig. 13.23. Such an impact would be very noticeable. The addition to economic growth would be close to 0.8% per year over the first 30 years but would then decrease, stopping after 40 years.

Social and political impacts

If the optimistic scenario were to occur and the increased cod harvest was mainly caught and processed by Greenlanders there would be a dramatic improvement in the Greenland unemployment/underemployment situation and in the income of the large group of self-employed small-boat fishers/hunters. Everything else being the same, the current high level of unemployment would disappear and the total income of many families would increase markedly. This would have a major social impact in Greenland. Cod fishing of the magnitude projected under the optimistic scenario might easily lead to the establishment of large-scale fish processing factories in the more densely populated regions of Greenland.

Under the pessimistic and moderate scenarios employment and consequently social impact would be far more moderate, especially if the changes appeared gradually over a long period. If, however, the change is sudden (as in the "dramatic" scenario for Iceland), short-term social and political impacts may be drastic.

Discussion

The likely impacts of the possible changes in fish stock availability in Greenland waters resulting from climate change cover a wider range than for Iceland. At one extreme, they could lead to a 30% increase in GDP, while at the other extreme the impact on GDP could be negligible. This range in outcomes reflects (1) the greater importance of the fisheries sector in Greenland compared to Iceland and (2) that during warm periods the very large marine habitat around Greenland can accommodate a biomass of commercial species which is many times greater than that at present. Since the arctic influence is more pronounced in the Greenland marine environment than in that around Iceland, it follows that impacts resulting from a moderate climate change, if it occurs, are very likely to be more dramatic in the marine environment around Greenland.

13.3.7. Ability to cope with change

Climate change will almost certainly lead to changes in the relative sizes, biological productivity, and spatial distribution of commercial fish stocks. These changes may be predominantly advantageous or predominantly disadvantageous. They may be sudden or may emerge gradually.

The economic and social impacts of changes in fish stock availability depend on the direction, magnitude, and rapidity of these changes. The economic and social impacts also depend, possibly even more so, on the ability of the relevant social structures to adapt to altered conditions. Good social structures facilitate fast adjustments to new conditions and thus mitigate negative impacts. Weak or inappropriate social structures exhibit sluggish and possibly inappropriate responses and thus may exacerbate problems resulting from adverse environmental changes.

One of the most crucial social structures in this respect is the fisheries management system. This determines the extent to which the fisheries can adapt in an optimal manner to new conditions. Other important social structures relate to (1) the adaptability of the economic system – especially price flexibility, labor education and mobility, and the extent of economic entrepreneurship; (2) the ability to adjust macro-economic policies; and (3) the extent and nature of the social welfare system. These structures influence the form of the necessary adjustments to new conditions, for example whether they are smooth and quick or difficult and long-term.

The Icelandic fisheries management system is based on permanent harvest shares in the form of ITQs and so is inherently forward-looking and thus probably well-suited to adjust optimally to changes in the availability of fish, especially if these changes are to an extent foreseen. For any time path of fish stock productivity, ITQ-holders have a strong incentive to maximize the expected present value of the fishery as this will also maximize their expected wealth. As a result, there is a high likelihood that TACs and other stock size determinants will be adjusted optimally to altered conditions. In other words, with the Icelandic fisheries management system, there is little chance that the fishing activity will exacerbate a negative biological impact arising from climate change. Also, the opportunities generated by a positive biological impact will probably be close to fully exploited by the fishing sector. In Greenland, however, fishers' rights to harvest shares are considerably weaker. As a result, Greenland seems less prepared than Iceland to adapt in an economically efficient manner to changed fish stock availability.

For the other relevant social structures, it also appears that those in Iceland are well-suited to facilitating adjustment to adverse environmental changes. First, Icelandic social structures are used to having to adapt to quite drastic fluctuations in the economy (see section 13.3.5.1), which implies that these institutions have evolved to cope with such fluctuations. Second, labor education and mobility is high in Iceland. High labor mobility refers to labor movements within Iceland as well as to between Iceland and other countries. This means that negative regional impacts resulting from climate change are unlikely to lead to permanently depressed unemployment areas or even persistent national unemployment. Third, the level of private and commercial entrepreneurship is

high in Iceland. This suggests that in the case of negative impacts, economic substitute activities are likely to be quickly spotted and exploited. Fourth, there is an extensive social welfare system in Iceland that would provide at least temporary compensation to individuals adversely affected by environmental change. Although this social "safety net" will tend to delay adjustments to new conditions, it will also ensure that the burden of adverse changes is shared among the total population and so prevents individual hardship.

Thus, broadly speaking, it appears that Icelandic social structures are well suited to cope with sudden changes in fish stock availability resulting from climate change. This means that adjustments to changes are likely to be fast and smooth. Adverse environmental changes will nevertheless be economically and socially costly. However, they are unlikely to be exacerbated by social and economic responses. On the other hand, although the Icelandic economy seems well prepared to deal with changes in fish stock availability, an adverse biological impact may be felt more strongly than in the past. This is because some of the most valuable commercial stocks are currently close to their historical minimum. Hence, if there is an adverse environmental change, the initial reduction in harvests may be more dramatic than previously experienced and, also, the risk of a long-tem stock depression greater.

The ability of social structures in Greenland to adjust to new conditions is similar to the situation in Iceland. Greenlanders are used to variable environmental and economic conditions. Although perhaps not at the level of Iceland, general education and labor training is also high in Greenland. However, partly due to the size of Greenland and the isolation of many communities, labor mobility is considerably less than in Iceland. Most importantly, however, the degree of private and commercial entrepreneurship in Greenland seems much less than in Iceland.

Thus, while the Greenland social structure and institutions seem reasonably well placed to adjust to the changes in fish stock availability that might result from climate change, they presently appear less suited in this respect than those in Iceland.

13.3.8. Concluding comments

The ecosystems of Iceland and Greenland are very different. Icelandic waters occur to the south of the Polar Front under normal circumstances and are therefore under the influence of warm Atlantic water. Greenland waters are dominated by the cold East Greenland Current. This difference is reflected in higher numbers of exploited species at Iceland than at Greenland where there is also a dominance of arctic species of plankton, commercial invertebrates, and fish.

Both ecosystems were subject to large climatic changes in the 20th century. After a prolonged period of cold conditions (lasting several decades), a warm period started around 1920 and peaked in the 1930s. Conditions were cooler in the 1940s, but warmed again and stayed warm for several years. There was a sudden cooling associated with decreased salinity and severe ice conditions in the mid-1960s. These changes reverberated around the North Atlantic at least twice during the next two decades. Conditions improved at Iceland in 1972 but remained variable for the next two and a half decades. Since the late 1990s, conditions have been persistently warmer at Iceland and even more so off West Greenland.

The warming of the 1920s and the early 1930s was followed by spectacular changes in the fish fauna of Icelandic and, in particular, Greenlandic waters. Cod and herring began to spawn in large numbers off the north coast of Iceland in addition to the traditional spawning areas in the Atlantic water off the south and west coasts. For some years, capelin were absent from their usual spawning areas to the south and west of Iceland, but spawned instead off southeast Iceland as well as in fjords and bays on the north and east coasts. Despite searches by Danish biologists and fishers, almost no cod were found to the south and west of Greenland between 1900 and 1920. However, after 1920 cod began to appear in increasing numbers in these areas and in the 1930s a cod fishery off West Greenland yielded on average about 100 000 t per year. This change is attributed to a massive drift of 0-group cod from Iceland across the northern Irminger Sea to the east and then west of Greenland.

Other changes associated with the warm period were manifested in a regular appearance of more southerly species such as mackerel and tuna at Iceland, while cold-temperate species such as haddock, saithe, and herring became fairly common at Greenland. In the latter case, cod extended their distribution northward to the west of Greenland for hundreds of kilometers to Disco Bay. Likewise, the center of capelin distribution shifted from off southwest Greenland to the Disco Bay area and the northern limit of their distribution reached as far as Thule.

Although many of the cod which had drifted across to Greenland as juveniles returned to spawn in their native areas off south and west Iceland, many did not, but spawned instead off West Greenland and eventually gave rise to a self-sustaining Greenlandic cod component. The Greenland cod were very successful for a number of decades and eventually formed a large local stock that supported catches in the hundreds of thousands of tonnes.

The cooling of the mid-1960s had a devastating effect, both at Iceland and Greenland. The spawning of cod at Greenland seems to have ceased completely and the stock crashed. At Iceland, the zooplankton community in the north and east changed from an atlantic to an arctic type. The most drastic effect was the disappearance of the Norwegian spring-spawning herring (the largest known

herring stock in the world) from its traditional feeding areas north of Iceland. In the following years the herring fed further east in the Norwegian Sea until the stock crashed in the late 1960s. The two local and much smaller Icelandic herring stocks suffered the same fate. These stocks were all subject to a large fishing pressure in the 1960s. While the collapses in the herring stocks can be traced to exploitation beyond sustainable levels, this is not the case for the Greenland cod stock. Although the stock was also heavily fished, and its downfall accelerated by the fishery, evidence suggests that cod cannot reproduce effectively at Greenland except under warm climatic conditions. On the other hand, the low temperatures of the latter 1960s and relatively cold but variable conditions of Icelandic waters since the early 1970s do not seem to have adversely affected the Icelandic cod stock. The relatively low abundance of cod at Iceland at present appears to be the result of overfishing.

From a socio-economic point of view, climate-driven changes in fish abundance at Iceland over the 20th century had very large effects. In particular, the disappearance of the Atlanto-Scandian herring had severe consequences at all levels of society. Iceland lost about half its foreign revenue from fish products almost instantly, resulting in severe economic depression. However, the depressed state did not last long. The herring sector of the fishery quickly targeted other local species and also shifted to fishing herring elsewhere, mainly in the North Sea and adjacent waters. The Icelandic fishery sector also adapted quickly to various fishing restrictions imposed during the last quarter of the 20th century.

The lucrative cod fishery, which started off West Greenland in the late 1920s and lasted until the stock collapse in the early 1970s, did not have much effect on

the Greenland economy. This was because the lack of suitable vessels and gear, as well as the necessary infrastructure, meant Greenland was unable to benefit from these conditions except on a very small scale.

Three scenarios of possible future climate change (no change, moderate warming (1–3°C), and considerable warming (4°C or more)) were used to examine likely outcomes for Iceland and Greenland. Changes in the size and distribution of commercial stocks are very unlikely under the no-change scenario. Thus, the Greenlandic fishing sector would mainly depend on cold water fish such as Greenland halibut and invertebrates such as northern shrimp and snow crab. At Iceland, fish species such as Atlantic cod, haddock, saithe, and redfish would dominate demersal fisheries, while capelin, local herring, and possibly blue whiting would dominate the pelagic fisheries. Catches of some species under the no-change scenario could be increased considerably through effective fisheries management, particularly in Iceland.

Moderate warming is likely to result in quite large positive changes in the catch of many species. Through larval drift from Iceland, a self sustaining cod stock is likely to be established off West Greenland which could yield annual catches of around 300 000 t. If that happens, catches of northern shrimp are likely to decrease to about 30% of the present level, while catches of snow crab and Greenland halibut are not likely to alter much. Such changes would probably approximately double the export earnings of the Greenland fishing industry, which roughly translates into the sum presently paid by Denmark to subsidize the Greenland economy. Such dramatic changes are not likely in the Icelandic marine ecosystem. Nevertheless, it is likely that there will be an overall gain through larger catches of demersal species such as cod, and pelagic species such as herring, and new fisheries of more southern species such as mackerel. On the other hand, capelin catches are likely to decrease, both through diminished stock size and the necessity of conserving this important forage fish for other species. Effective fisheries management is very likely to continue to play a key role for Greenland and Iceland.

Little can be said about potential changes under the scenario of considerable warming. This is because such a situation is outside any recorded experience.

13.4. Newfoundland and Labrador Seas, Northeastern Canada

Fisheries in ACIA Region 4 may be subdivided into those near the coast of Greenland, those near the coast of Canada, and those in the deep waters of Baffin Bay and Davis Strait between Greenland and Canada. The whole area is within the fisheries convention area of NAFO (Fig. 13.24) and the stocks are currently managed by the coastal state or by NAFO.

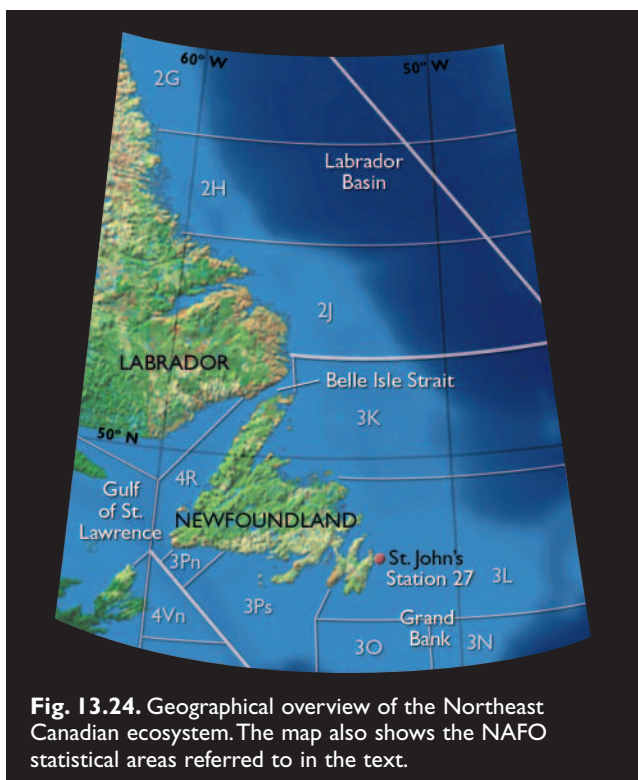
Along the northeast coast of Canada the study area extends southward to the central Grand Bank (46° N) in


Fig. 13.24. Geographical overview of the Northeast Canadian ecosystem. The map also shows the NAFO statistical areas referred to in the text.

order to assess climate-driven impacts on marine ecosystems that are comparable to those considered for the northeast Atlantic (section 13.2) and around Iceland (section 13.3). This southward extension reflects the presence of the Labrador Current, which transports cold water southward from Davis Strait, the Canadian Archipelago, and Hudson Bay. The median southerly extent of sea ice is on the northern Grand Bank at approximately 47° N (Anon, 2001) and bottom water temperatures on the northern Grand Bank are below 0 °C for long periods. The southerly extent of cold conditions is also indicated by the regular presence of polar cod along the northeast coast of Newfoundland and their occasional occurrence on the northern Grand Bank (Lilly and Simpson, 2000; Lilly et al., 1994).

Fish has dominated the history of Newfoundland since the time of British colonization. The British interest in Newfoundland after its "discovery" during the Cabot voyage of 1497 was due to the incredibly large amounts of codfish. Exploitation of this fishery by the British reduced its dependence on Iceland for fish, a dependence that was creating difficulties. The French also saw the value of Newfoundland's fishery, and possession of the island became an important part of the colonial wars of the 18th century (for the historical background of Newfoundland, see Chadwick, 1967; Innis, 1954; Lounsbury, 1934). As an inducement for France to enter the revolutionary war on the side of the American colonies, Benjamin Franklin offered a share of the Newfoundland fishery to the French as bounty once the war was won (Burnett, 1941). Indeed, until the late 1800s, when a cross-island railroad was built, fishing was Newfoundland's only industry. There was then a series of diversification programs, which have continued in one form or another until the present day. Although in the early 1970s Newfoundland had the world's largest hydroelectric plant (in Labrador), and despite many attempts to diversify the economy with both small-scale industries (e.g., cement production, knitting mills, a shoe factory, a chocolate factory) and numerous large-scale industries (e.g., the Churchill Falls hydroelectric station, a petroleum refinery, a third paper mill, iron mines in Labrador) in the twenty years following Confederation with Canada in 1949, none of these made any difference to the dominance of the fishery in Newfoundland (Letto, 1998). However, what did change in Newfoundland with Confederation, and after revisions in Canadian federal/provincial intergovernmental arrangements, was the emergence of extremely large government, health, and education sectors which, as shares of GDP, eclipsed the fishery. By 1971, the fish and fish processing sectors accounted for less than 5% of Newfoundland GDP. By 2001, their contribution was 3.5 %.

13.4.1. Ecosystem essentials

The ecosystem off northeastern Canada has been characterized by a relatively small number of species, a few of which have historically occurred in high abundance

(Bundy et al., 2000; Carscadden et al., 2001; Livingston and Tjelmeland, 2000). The dominant fodder fish has been capelin, with polar cod more prominent to the north and sand lance (*Ammodytes dubius*) more prominent to the south on the plateau of Grand Bank. Herring is found only in the bays and adjacent waters. These four species of planktivorous fish feed mainly on calanoid copepods and larger crustaceans, the latter predominantly hyperiid amphipods to the north and euphausiids to the south. The dominant piscivorous fish has been Atlantic cod, but Greenland halibut and American plaice (*Hippoglossoides platessoides*) have also been important. Snow crab and northern shrimp have been the dominant benthic crustaceans. The top predators are harp seals and hooded seals which migrate into the area from the north during late autumn and leave in spring. Other important predators include whales, most of which migrate into the area from the south during late spring and leave during autumn. The most important are humpback (*Megaptera novaeangliae*), fin, minke, sei, sperm, and pilot whales (*Globicephala melaena*). Additional immigrants from the north during the winter include many birds, such as thick-billed murre, northern fulmar (*Fulmarus glacialis*), and little auk. Additional immigrants from the south during summer include short-finned squid, fish such as mackerel and bluefin tuna (*Thunnus thynnus*), and birds such as greater shearwater (*Puffinus gravis*) and sooty shearwater (*P. griseus*).

The Labrador/Newfoundland ecosystem has experienced major changes since 1980. Atlantic cod and most other demersal fish, including species that were not targeted by commercial fishing, had declined to very low levels by the early 1990s (Atkinson, 1994; Gomes et al., 1995). In contrast, snow crab (DFO, 2002a) and especially northern shrimp (DFO, 2002b) increased considerably in abundance during the 1980s and 1990s and now support the most important fisheries in the area. Harp seals increased in abundance between the early 1970s and the mid-1990s (DFO, 2000c). Capelin have been found in much reduced quantities in offshore acoustic surveys since the early 1990s, but indices of capelin abundance in the inshore surveys have not shown similar declines, leaving the status of capelin uncertain and controversial (DFO, 2000b, 2001). Atlantic salmon, the major anadromous fish in the area, has declined in abundance, due in part to lower survival at sea (DFO, 2003b; Narayanan et al., 1995).

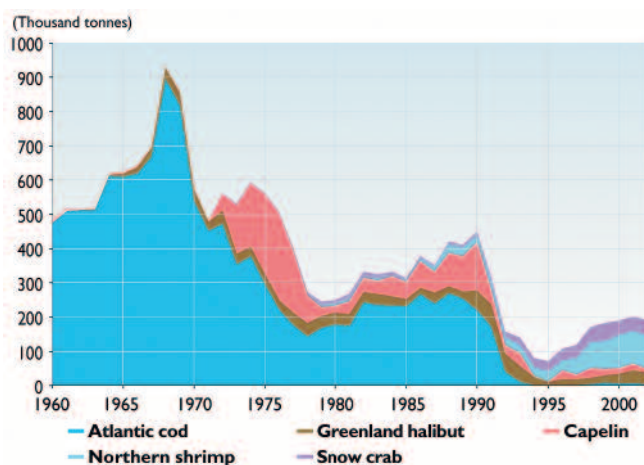
The waters of eastern Newfoundland have been fished for centuries, primarily for Atlantic cod but with an increasing emphasis on other species during the latter half of the 20th century. These fisheries have undoubtedly had an influence on both the absolute abundance of some species and the abundance of species relative to one another. However, the role of the fisheries in structuring the ecosystem is often difficult to distinguish from the role of changes in the physical environment. The area cooled during the last three decades of the 20th century, with particularly cold periods in the early 1970s, early to mid-1980s, and early 1990s. This cooling, which was


Fig. 13.25. Total catch of selected species off northeastern Canada, 1960–2002 (data from NAFO STATLANT 21A online database www.nafo.int/activities/FRAMES/AcFrFish.html; Anon, 2004a; Darby et al., 2004; Dawe et al., 2004; Hvingel, 2004; Lilly et al., 2003; Murphy and Bishop, 1995; Orr et al., 2003, 2004; Stenson et al., 2000).

associated with an intensification of the positive phase of the North Atlantic Oscillation (Colbourne and Anderson, 2003; Colbourne et al., 1994; Mann and Drinkwater, 1994; Narayanan et al., 1995), may have played an important role in the dramatic decline in Atlantic cod and other demersal fish, and the increase in crustaceans, especially northern shrimp.

13.4.2. Fish stocks and fisheries

Catches are from official NAFO statistics (as of February 2004) or from relevant assessment documents if there is a difference between the two (e.g., NAFO 2001a,b). Figure 13.25 provides an overview of developments in the main fisheries off Newfoundland and Labrador since 1960.

13.4.2.1. Atlantic cod

The distribution of Atlantic cod off Canada has historically been from the northern Labrador Shelf southward to beyond the limit of this study, although during the 1990s there were few cod off Labrador. Atlantic cod tends to occur on the continental shelf, but has been
Fig. 13.26. Catch of Atlantic cod, 1960–2002 (data from Murphy and Bishop, 1995; Lilly et al., 2003).

found at depths of at least 850 m on the upper slope off eastern Newfoundland (Baird et al., 1992).

The European fishery for Atlantic cod off eastern Newfoundland began in the late 15th century. For the first few centuries fishing was by hook and line, so the cod were exploited only from late spring to early autumn and only in shallow water along the coast and on the plateau of Grand Bank to the southeast of the island. There is evidence that local inshore over-exploitation was occurring in the 19th century (Cadigan, 1999), but improvements in gear and an increase in the area fished tended to compensate for local reductions in catch rate. Annual landings increased through the 18th and 19th centuries to about 300 000 t in the early 20th century. The deep waters were refugia until the 1950s, when larger vessels with powered gurdys were introduced to exploit cod in deep coastal waters and European trawlers started to fish the deeper water on the banks. Landings increased dramatically in the 1960s as large numbers of trawlers located and exploited the overwintering aggregations on the edge of the Labrador Shelf and the Northeast Newfoundland Shelf. At the same time, the numbers of large cod in deep water near the coast of Newfoundland are thought to have declined quickly as the longliner fleet switched to synthetic gillnets. Catches peaked at 894 000 t in 1968, and then declined steadily to only 143 000 t in 1978. Following Canada's declaration of a 200 nm EEZ in 1977, the stock recovered slightly and catches were between 230 000 and 270 000 t for most of the 1980s. However, catches fell rapidly in the early 1990s as the stock declined to very low levels. A moratorium on directed fishing was declared in 1992 (Fig. 13.26). A small cod-directed inshore fishery was opened in 1998 but closed in 2003. Additional details on the history of the Atlantic cod fishery of Newfoundland and Labrador, including changes in technology and temporal variability in the spatial distribution of fishing effort, may be found in Templeman (1966), Lear and Parsons (1993), Hutchings and Myers (1995), Lear (1998), Neis et al. (1999), and Hutchings and Ferguson (2000).

13.4.2.2. Greenland halibut

Greenland halibut (also called Greenland turbot) is distributed off West Greenland from Cape Farewell northward to about 78° N and then southward off eastern Canada to beyond the limit of this study. It is a deep-water species, occurring at depths from about 200 m to at least 2200 m off West Greenland (Bowering and Brodie, 1995). The history of the fishery is complicated by temporal and spatial variation in effort and catch by different fleets and by alleged underreporting of landings. For details of the fisheries, refer to Bowering and Brodie (1995), Bowering and Nedreaas (2000), and NAFO (2001b).

The fishery off eastern Newfoundland dates back to the mid-19th century (Bowering and Brodie, 1995; Bowering and Nedreaas, 2000). Annual catches from
Fig. 13.27. Catch of Greenland halibut, 1960–2002 (data from NAFO STATLANT 21A online database www.nafo.int/activities/FRAMES/AcFrFish.html; Darby et al., 2004).

Fig. 13.28. Catch of capelin, 1960–2002 (data from NAFO STATLANT 21A online database www.nafo.int/activities/FRAMES/AcFrFish.html).

longlines were less than 1000 t until the early 1960s, when catches began to increase substantially. Landings from offshore trawlers, mainly from European countries, also increased after the mid-1960s. Catches in SA 2 + Div. 3KL fluctuated around 25 000 to 35 000 t from the late 1960s to the early 1980s, after which there was a gradual decline to about 15 000 t in 1986. Landings increased dramatically in 1990 with the arrival of many non-Canadian trawlers that fished deep waters on the northern Grand Bank (see Fig. 13.24 for location). Catches over the next four years were high (estimated at between 55 000 and 75 000 t in 1991; NAFO, 2001b), declined substantially in 1995 due to an international dispute, and increased again in the late 1990s under NAFO quotas that maintained catches well below those of the early 1990s (Fig. 13.27).

The fishery to the north (NAFO SA 0), which has been conducted primarily with otter trawlers in the second half of the year (Bowering and Brodie, 1995), reported an average annual catch of 2100 t between 1968 and 1989 (including a high of 10 000 t in 1972). Catches increased dramatically to 14 500 t in 1990 with increased effort by Canada, but declined to about 4000 t from 1994 onward. These landings came mainly from off southeastern Baffin Island. The fishery expanded even further north into Baffin Bay in the mid- to late 1990s (Treble and Bowering, 2002). This fishery, which extended to 73° N in 2002 (M.A. Treble, Fisheries and Oceans Canada, pers. comm., 2003), has been limited by sea-ice cover in September through November.

13.4.2.3. Capelin

Before the start of a commercial offshore fishery in the early 1970s, capelin were fished on or near the spawning beaches. Annual catches, used for local consumption, may have reached 20 000 to 25 000 t (Templeman, 1968). Offshore catches by foreign fleets increased rapidly, peaking in 1976 at about 250 000 t, and then declined rapidly. This offshore fishery continued at a low level until 1992. Catches in the offshore fishery were taken at different times of the year in different areas. The spring fishery was dominated by large midwater trawlers operating in Div. 3L. During the autumn, the offshore fishery first

occurred in Div. 2J, off the coast of Labrador, and gradually moved south into Div. 3K as the capelin migrated toward their overwintering area (see Fig. 13.24 for NAFO statistical areas). This fishery was also dominated by large midwater trawlers, which mostly took feeding capelin that would spawn the following year. During the late 1970s, as the foreign fishery declined, Canadian fishers began fishing mature capelin near the spawning beaches to supply the Japanese market for roe-bearing females. This fishery expanded rapidly, exhibited highest catches during the 1980s, and declined over the 1990s. Catches in the inshore fishery have generally been lower than from the offshore fishery. The total international catch of capelin off Newfoundland and Labrador from 1960 to 2002 is shown in Fig. 13.28.

13.4.2.4. Herring

Herring in the Newfoundland and Labrador area are at the northern extent of their distribution. Stocks are coastal in distribution and stock abundance is low compared to other stocks in the Atlantic. A peak catch of 30 000 t occurred in 1979, supported by strong year classes from the 1960s. Recruitment since the 1960s has been lower. Stock sizes in the late 1990s were less than 90 000 t and annual catches less than 10 000 t (DFO, 2000a).

13.4.2.5. Polar cod

Polar cod is broadly distributed through the Arctic and in cold waters of adjacent seas. It occurs on the shelf from northern Labrador to eastern Newfoundland, with the average size of individuals and the size of aggregations decreasing from north to south (Lear, 1979). There has been no directed fishery for polar cod off eastern Canada, but a small bycatch was reported in the Romanian capelin fishery in 1979 (Maxim, 1980), and it is likely that small quantities were also taken in other years and by other countries.

13.4.2.6. Northern shrimp

Northern shrimp is distributed off West Greenland from Cape Farewell northward to about 74° N and then
Fig. 13.29. Catch of northern shrimp, 1960–2002 (data from NAFO STATLANT 21A online database www.nafo.int/activities/ FRAMES/AcFrFish.html; Hvingel, 2004; Orr et al., 2003, 2004).

southward off eastern Canada to beyond the limit of this study. The depth of highest concentration tends to vary from area to area but is generally between 200 to 600 m. A fishery with large trawlers began off north-eastern Canada in the late 1970s (Orr et al., 2001a). For the first decade most of the catch was taken from two channels in the central and southern Labrador Shelf, but in the late 1980s there was an increase in effort and landings both to the south on the Northeast Newfoundland Shelf and to the north off northern Labrador. Catches increased above 25 000 t by the mid-1990s. New survey technology introduced in 1995 indicated that commercial catches were very small relative to survey biomass, and quotas were increased considerably in the late 1990s. Total landings rose to more than 90 000 t by 2000 (Fig. 13.29). Much of the increase in catch from 1997 onward was from a new fleet of small (<100 feet) vessels that fished with bottom trawls mainly on the mid-shelf. In the 1990s fishing also expanded to Div. 3L (Orr et al., 2001b).

13.4.2.7. Snow crab

Snow crab is distributed from the central Labrador Shelf at approximately 55° N southward off eastern Canada to beyond the limit of this study. The depth distribution extends from approximately 50 to 1400 m, but most of the fishery occurs at 100 to 500 m. The fishery off eastern Newfoundland began in the late
1960s as a small bycatch fishery, but soon expanded into a directed fishery with crab traps (pots) along most of the inshore areas of eastern Newfoundland (Div. 3KL) (Taylor and O'Keefe, 1999). During the late 1970s and early 1980s there was an increase in effort and an expansion of fishing grounds. Catches in Div. 3KL reached almost 14 000 t in 1981, but then declined. In the mid-1980s there was expansion of the fishery to the area off southern Labrador (Div. 2J) and new entrants gained access to supplement declining incomes from the groundfish fisheries. The number of participants and the area fished expanded further during the 1990s, and total catches rose quickly, reaching almost 55 000 t in 1999. Quotas and landings were reduced for the next two years following concerns that the resource may have declined.

Commercial catch rates in Div. 3KL increased during the late 1970s to a peak in about 1981, declined to their lowest point by 1987, and then increased in the late 1980s and early 1990s to a level comparable to that in the early 1980s (DFO, 2002a). Catch rates remained high to the end of the 1990s, despite the substantial increase in fishing effort and landings (Fig. 13.30). This partly reflects an increase in the area fished, although there must also have been an increase in productivity.

13.4.2.8. Marine mammals

Harp seals summer in the Canadian Arctic or Greenland but winter and breed in Canadian Atlantic waters. There are two major breeding groups: the first breeding in the Gulf of St. Lawrence and the second breeding off southern Labrador and northeast Newfoundland (Bundy et al., 2000). The total population increased from less than 2 million in the early 1970s to more than 5 million in the mid-1990s (Healey and Stenson, 2000; Stenson et al., 2002). The increase was largely due to a reduction in the hunt after 1982 (Stenson et al., 2002). The population stabilized when the hunt was increased in the mid-1990s. Reported Canadian catches of harp seals include

Fig. 13.30. Catch of snow crab, 1960–2002 (data from NAFO STATLANT 21A online database www.nafo.int/activities/ FRAMES/AcFrFish.html; Hvingel, 2004; Orr et al., 2003, 2004).

Fig. 13.31. Catch of harp and hooded seals, 1952–2002. The catches also include seals taken in the Gulf of St. Lawrence (data from Anon, 2004a; Stenson et al., 2000).

harvests off the coast of Newfoundland/Labrador (the "Front") and in the Gulf of St. Lawrence. Seals caught in both areas belong to the same population: the Northwest Atlantic Harp Seals. The proportion of the population that occurs in the two areas varies among years, as does the relative number of seals caught in each area. Catches from both areas are combined in official statistics and so those presented here are combined "Front" and Gulf of St. Lawrence catches (Fig. 13.31).

Hooded seals are less abundant than harp seals. Whelping occurs on pack ice off northeast Newfoundland, in Davis Strait, and in the Gulf of St. Lawrence. Pups migrate into arctic waters and remain there as juveniles. Adults migrate south in the autumn and return to the Arctic in April (Bundy et al., 2000). The harvest of hooded seals ("Front" and Gulf of St. Lawrence combined) is shown in Fig. 13.31.

There has been no commercial whaling in the area since the late 1970s. Using north Atlantic population estimates, assumed growth rates, and an assumed proportion of the total population in the Newfoundland and Labrador area, Bundy et al. (2000) estimated population abundances of 33 000 for humpback whales, 1000 for fin whales, 5000 for minke whales, 1000 for sperm whales, 1000 for sei whales, and 9000 for pilot whales.

13.4.3. Past climatic variations and their impact on commercial stocks

13.4.3.1. Atlantic cod

The severe decline in Atlantic cod in the Newfoundland and Labrador area seems to have occurred from north to south. On the northern and central Labrador shelf (Div. 2GH), catches of 60 000 to 90 000 t were reported for the period 1965 to 1969, but catches declined to less than 5000 t for most of the 1970s and early 1980s, and to less than 1000 t in the latter half of the 1980s (Fig. 13.32). There are no analyses of factors that contributed to the decline in this area.
Fig. 13.32. Catch of Atlantic cod by NAFO statistical division, 1960–2000 (data from Murphy and Bishop, 1995; Lilly et al., 2003).

In the area from southern Labrador to the northern Grand Bank, the Div. 2J+3KL stock (the so-called "northern cod") collapsed in the 1970s in response to severe overfishing. The stock recovered slightly in the 1980s but collapsed to even lower levels in the late 1980s and early 1990s. There is controversy as to whether there was a rapid but progressive decline from the mid-1980s onward or a precipitous decline in the early 1990s (Atkinson and Bennett, 1994; Shelton and Lilly, 2000). Many studies (e.g., Haedrich et al., 1997; Hutchings, 1996; Hutchings and Myers, 1994; Myers and Cadigan, 1995; Myers et al., 1996a,b, 1997a,b) have concluded that the final stock collapse was entirely due to fishing activity (landed catch plus discards). However, several authors have pointed to ways in which the decline in water temperature and increase in sea-ice cover might have contributed to the collapse, either directly by reducing productivity (Drinkwater, 2000, 2002; Mann and Drinkwater, 1994; Parsons L. and Lear, 2001) or indirectly by affecting distribution (Rose et al., 2000).

Despite many studies on this cod stock, there are few uncontested demonstrations of the influence of climate variability on stock dynamics. There is an expectation that recruitment might be positively influenced by warm temperatures, because the stock is at the northern limit of the species' range in North America (Planque and Frédou, 1999). However, there have been conflicting reports of whether such a relationship can be detected (deYoung and Rose, 1993; Hutchings and Myers, 1994; Planque and Frédou, 1999; Taggart et al., 1994). Part of the problem is that recruitment is also positively influenced by the number and size of spawners in the population (the spawning stock biomass or SSB; Hutchings and Myers, 1994; Morgan et al., 2000; Myers et al., 1993; Rice and Evans, 1988; but see Drinkwater, 2002). Both temperature and SSB declined from the 1960s to the 1990s, increasing the difficulty of demonstrating a temperature effect. A reported positive relationship between recruitment and salinity (Sutcliffe et al., 1983) was subsequently supported (Myers et al., 1993) and later rejected (Hutchings and Myers, 1994; Shelton and Atkinson, 1994) as data for additional years became available. The negative effect of temperature on individual growth has been well documented (Krohn et al., 1997; Shelton et al., 1999). Additional aspects of cod biology that changed during the early 1990s, possibly in response to changes in the physical environment, include a delay in arrival on traditional inshore fishing grounds in early summer (Davis, 1992), a concentration of distribution toward the shelf break in autumn (Lilly, 1994; Taggart et al., 1994), a move to deeper water in winter (Baird et al., 1992), and an apparent southward shift in distribution (Kulka et al., 1995; Rose and Kulka, 1999; Rose et al., 1994).

Of much interest is the possibility that an increase in natural mortality contributed to the rapid disappearance of cod in the early 1990s. The sharp decline in survey abundance indices occurred during a period of

severe cold and extensive sea-ice cover. A considerable decline in the condition of the cod occurred at the same time, especially in the north (Bishop and Baird, 1994; Lilly, 2001). Steep declines in abundance also occurred among other groundfish in the 1980s and 1990s (Atkinson, 1994; Gomes et al., 1995), and while there have been some suggestions that these declines were caused by captures during fishing for cod and other species (Haedrich and Barnes, 1997; Haedrich and Fischer, 1996; Haedrich et al., 1997; Hutchings, 1996), there is no direct evidence of large removals. In the case of American plaice, a species studied in detail, Morgan et al. (2002) demonstrated that the declines were too large to have resulted from fishing alone. The contribution of increased natural mortality to the decline in cod and other demersal fish in this area during the last two decades of the 20th century, and particularly during the early 1990s, remains unresolved (Lilly, 2002; Rice, 2002).

The northern cod stock was still at a very low level a decade after the moratorium on directed fishing (DFO, 2003a; Lilly et al., 2001). Recruitment to ages 0 to 2 remained very low, possibly due in part to a very small spawning stock biomass; juveniles in the offshore areas appeared to show very high mortality, possibly due in part to predation by harp and hooded seals; and a directed fishery during 1998 to 2002 targeted the inshore aggregations, resulting in increased mortality on the larger fish. The unquantified impacts of low spawning stock biomass, high predation, and fishing make it difficult to establish whether some aspect of ocean climate has had a role in impeding recovery.

13.4.3.2. Greenland halibut

The status of Greenland halibut in the northwest Atlantic has been uncertain because the stock structure is still unclear, the fish have extensive ontogenetic migrations, there appear to have been shifts in distribution, the fisheries have undergone many changes in fleet composition and in areas and depths fished, and individual research surveys have only covered part of the distribution range. Nevertheless, evidence suggests that the biomass of Greenland halibut on the western side of the Labrador Sea declined substantially during the 1980s, with the decline off Baffin Island and northern Labrador (Div. 0B and 2GH) most pronounced in the first half of the decade and the decline off southern Labrador and eastern Newfoundland (Div. 2J3K) to the south most pronounced in the latter half of the 1980s and the early 1990s (Bowering and Brodie, 1995). Evidence for a decline in biomass in Div. 2J3K is also seen in the declining success of the gillnet fishery in the 1980s. The history of the fish exploited during the 1990s by the new deep-water trawler fishery to the south on the northern Grand Bank (Div. 3L) is less clear. At least some of these fish may have migrated into the area from the shelf to the north (Bowering and Brodie, 1995), in which case the decline in Div. 2J3K was partly due to a southward shift in distribution.

Reasons for the declines in biomass and shift in distribution remain unclear. Bowering and Brodie (1995) drew attention to the decline in water temperatures on the shelf in the early 1990s, but thought it unlikely that such a change would in itself have affected the distribution and abundance of Greenland halibut because this species occupies relatively deep water. Also, much of the shift in distribution must have occurred in the latter half of the 1980s, a period during which water temperatures were low but not as low as during the early 1990s.

Variability in the physical environment had no observed effect on either size at age (Bowering and Nedreaas, 2001) or maturity at size or age (Morgan and Bowering, 1997) between the late 1970s and mid-1990s.

13.4.3.3. Capelin

The relationship between capelin biology and the physical environment has been extensively studied in the Newfoundland and Labrador area. Of particular relevance to this assessment is the observation that many aspects of capelin biology changed during the 1990s and, initially, it appeared that these were the result of changes in water temperature. However, water temperatures in the latter half of the 1990s returned to normal while the biological changes exhibited by capelin did not revert to earlier patterns. There are many environmental variables that are linked to capelin biology which may be relevant in the event of global climate change and these are briefly described in the rest of this section.

Mean fish length of the mature population was smaller during the 1990s (Carscadden et al., 2002). These small sizes have been attributed to smaller fish sizes at age with fewer older and more younger fish in the population. Condition (calculated as a relationship between length and weight and regarded as a measure of "well-being") of capelin was generally higher in the 1980s than the 1990s. Condition was not related to temperature (Carscadden and Frank, 2002).

Spawning occurs most often on fine gravel and grain size and beach orientation have been shown to explain 61% of the variation in egg concentration among beaches (Nakashima and Taggart, 2002; Vilhjálmsson, 1994). Water temperature is also a determinant of capelin spawning. The lowest and highest recorded temperatures for beach spawning in Newfoundland are 3.5 and 11.9 ºC, with beach spawning ceasing when temperatures exceed 12.0 ºC (Nakashima and Wheeler, 2002). Capelin eggs are very cold- and salinity-tolerant, surviving down to -5 ºC and in salinities from 3.4 to 34 (Davenport, 1989; Davenport and Stene, 1986). The rate of egg development in the beach gravel is directly related to average incubation temperatures, which in turn are determined by water temperature, maximum and minimum air temperature, and hours of sunlight (Frank and Leggett, 1981).

Some capelin that move close to spawning beaches eventually spawn in deeper water adjacent to beaches. This demersal spawning can occur simultaneously with intertidal spawning when temperatures are suitable as well as when water temperatures at the beach–water interface become too warm. Egg mortality among these demersal eggs has been observed to be higher. Reproductive success may have been lower during the 1990s because the water temperatures encountered when the capelin reached the spawning beaches would have increased the incidence of demersal spawning (Nakashima and Wheeler, 2002). Historically, the spawning of capelin off Newfoundland beaches in June and July was a predictable event. In the early 1990s, spawning was later, and 80% of the variation in spawning time (1978–1994) was significantly and negatively related to mean fish size and sea temperatures experienced during gonadal maturation (Carscadden et al., 1997). Spawning on Newfoundland beaches continued to be delayed through 2000 despite sea temperatures having returned to normal. However, mean lengths of capelin continued to be small.

There are historical reports of capelin occurring outside their normal distribution range. Unusual appearances in the Bay of Fundy and on the Flemish Cap were attributed to cooler water temperatures while occurrences in Ungava Bay coincided with warming trends (summarized by Frank et al., 1996).

In the early 1990s, capelin distribution occurred more to the south, centered on the northern Grand Banks. Originally attributed to the colder water temperatures (Frank et al., 1996), this shift within the normal distribution area continued through 2000. Because capelin did not return to their usual pattern of seasonal distribution as water temperatures increased, this suggests that factors other than water temperature were also operating. Outside their normal distribution area, capelin occurred on the Flemish Cap and eastern Scotian Shelf in the early 1990s and occasionally during earlier cold periods. Capelin continued to appear on the Flemish Cap and on the eastern Scotian Shelf through 2000. In this case, capelin appear to be gradually declining in abundance as the waters warm. For mature capelin offshore during spring, Shackell et al. (1994) concluded that temperature was not a proximate cue during migration but that seasonal temperatures moderated offshore capelin migration patterns through the regulation of growth, maturation, food abundance, and distribution.

Capelin typically move up and disperse throughout the water column at night, descending and aggregating at greater depths during the day. However, during spring surveys throughout the 1990s they remained deeper in the water column and exhibited reduced vertical migration (Mowbray, 2002; Shackell et al., 1994). This change in vertical distribution was not related to the several factors tested, including temperature and predation, but may have been linked to feeding success (Mowbray, 2002).

Recruitment of beach-spawning capelin is partly determined by the frequency of onshore winds during larval residence in the beach gravel (Carscadden et al., 2000; Leggett et al., 1984). Capelin assessments have been especially problematic since the early 1990s, resulting in considerable uncertainty in the status of the stock. However, there is no evidence to indicate that exploitation has had a direct effect on population abundance (Carscadden et al., 2001), suggesting that any variations in abundance are due to environmental factors. It is not known whether some changes in biology such as condition and distribution have affected abundance, however, spawning time and increased demersal spawning may be contributing to poor survival.

Thus, exploitation has not been shown to affect any aspect of capelin biology in this area. Although there have been several changes in capelin biology beginning in the early 1990s, there is no clear indication of what external factor(s) has (have) influenced the changes. Earlier studies concluded that temperature was an important factor for some changes, but it now seems unlikely that temperature is the sole factor, given that water temperatures have returned to normal. There are suggestions that changes in food supply (zooplankton) may be affecting capelin biology but the exact mechanisms have not been identified.

13.4.3.4. Herring

Recruitment is positively related to warm overwintering water temperatures and high salinities (Winters and Wheeler, 1987); these conditions seldom exist in this region and so, large year classes rarely occur.

13.4.3.5. Polar cod

The distribution of polar cod off eastern Newfoundland expanded to the south and east during the cold period of the early 1990s (Lilly and Simpson, 2000; Lilly et al., 1994).

13.4.3.6. Northern shrimp

The shrimp resource off northeastern Canada has increased in density and expanded in distribution since the mid-1980s. There is no indication that increased catches have negatively affected the resource (DFO, 2002b).

There is much support for the hypothesis that the increase in northern shrimp off northeastern Canada was, at least in part, a consequence of a reduced predation pressure by Atlantic cod and other groundfish (Bundy, 2001; Lilly et al., 2000; Worm and Myers, 2003). Nevertheless, there is evidence that other factors were involved. For example, Lilly et al. (2000) noted that the increase in shrimp density on the Northeast Newfoundland Shelf might have started in the early 1980s, a time when the biomass of Atlantic cod was increasing following its first collapse in the 1970s. Parsons D. and Colbourne (2000) found that catch per

unit effort in the shrimp fishery on the central Labrador Shelf was positively correlated with sea-ice cover six years earlier. They suggested that cold water or sea-ice cover itself was beneficial to the early life history stages of shrimp in that area.

13.4.3.7. Snow crab

The increased productivity of snow crab in the 1990s may have been caused, at least in part, by the release in predation pressure from Atlantic cod and other demersal fish (Bundy, 2001). However, the relationships between Atlantic cod and snow crab have not yet been explored to the same extent as for Atlantic cod and northern shrimp. A preliminary examination of the influence of oceanographic conditions on snow crab productivity has shown a negative relationship between ocean temperature and lagged catch rates (DFO, 2002a). This has been interpreted to indicate that cold conditions early in the life cycle are associated with the production of strong year classes of snow crab in this area.

13.4.3.8. Marine mammals

Trends in populations of marine mammals over recent decades appear to be influenced mainly by the commercial harvest. As populations of harp seals have increased in abundance, changes in biological characteristics indicate that density-dependence may be operating (Stenson et al., 2002). Density-independent influences may also regulate harp seal populations. Harp seals whelp on sea ice and mortalities may vary according to sea-ice conditions in this critical period. Mortalities of newly whelped pups may also occur during winter storms.

Concerns regarding the impact of predation by seals on commercial fish species increased as seal populations increased. It has been estimated that 74% (about 3 million t) of the total annual consumption by four species of seals in eastern Canada occurred off southern Labrador and Newfoundland (Hammill and Stenson, 2000). Predation by harp seals has been implicated in the lack of recovery of the northern cod stock (DFO, 2003a), and predation on cod by hooded seals may be large (DFO, 2003a).

13.4.3.9. Aquaculture

Salmonid aquaculture does not occur in the ACIA part of Newfoundland because the water is too cold in winter. The main species cultured is blue mussel. Production of this species has grown over the last twenty years such that, in 2002, around 1700 t were raised in the whole of Newfoundland.

13.4.4. Possible impacts of climate change on fish stocks

Two recent papers (Frank et al., 1990; Shuter et al., 1999) discussed the possible influence of climate change on ecosystems and fisheries off eastern Canada. Frank

et al. (1990) predicted shifts in the ranges of several groundfish stocks because of redistribution of populations and changing recruitment patterns. Stocks at the southern limit of a species' distribution should retract northward, whereas those near the northern limit should expand northward. Frank et al. (1990) did not make predictions specifically for Labrador and eastern Newfoundland, but events during the decade following publication of their paper were in many respects opposite to these general predictions. The changes off Labrador and eastern Newfoundland were unprecedented and not predicted, and illustrate the uncertainty of predictions, even on a regional scale and in the relatively short term. Shuter et al. (1999) had the advantage of witnessing the dramatic changes that occurred in the physical and biotic environment during the 1990s. They concluded that greenhouse gas accumulation will lead to a warmer, drier climate and, for the fisheries of Atlantic Canada, this will result in a "decrease in overall sustainable harvests for coastal and estuarine populations due to decreases in freshwater discharge and consequent declines in ecosystem productivity". For fisheries in the Arctic, they predicted "increases in sustainable harvests for most fish populations due to increased ecosystem productivity, as shrinkage of ice cover permits greater nutrient recycling".

As the relative importance of fishing and environment is difficult to determine for any species or group of species, it is not surprising that the importance attributed to each has varied for different studies. It is also not surprising, given the differences among species in the magnitude of fishery removals relative to stock size, that opinion favors fishing as the dominant factor for some species and environment for others. For demersal fish, there are many statements to the effect that declines were caused entirely by overfishing, but there is evidence that changes in oceanographic properties contributed to changes in distribution and declines in productivity. For crab and especially shrimp, it has been suggested that increases in biomass were simply a consequence of a release in predation pressure from Atlantic cod and perhaps other demersal fish, but again there is evidence that changes in oceanographic factors contributed to an increase in reproductive success. For capelin, most information supports the hypothesis that fishing had little impact on population dynamics, and that environmental factors were the primary determinant of stock size, well-being (growth and condition), distribution, and timing of migrations. For polar cod, fishing may be dismissed as a contributor to changes in distribution and biomass.

An important constraint on predicting changes in fish stocks and the fisheries that exploit them off Labrador and eastern Newfoundland is uncertainty about the direction and magnitude of change in important oceanographic variables. For surface air temperature, some model outputs project a cooling over the central North Atlantic, and it is not clear where the Labrador/ Newfoundland region lies within the gradation from

significant warming in the high Arctic to cooling over the central North Atlantic. In addition, there is no model for downscaling the output of general circulation models to specifics of the Labrador/Newfoundland area. As an example of the importance of regional models, many large-scale models project an increase in air temperature over the Norwegian and Barents Seas, while simulations with one specific regional model (Furevik et al., 2002) indicate that sea surface temperature in that area may decline in the next 20 years before increasing later in the century. Another concern is that natural variability in a specific region, such as the Labrador Shelf, may be greater than variability in the global mean (Furevik et al., 2002). Thus, a warming trend in shelf waters off Labrador and Newfoundland might be accompanied by substantial annual variability, such as was witnessed during the last three decades of the 20th century, and it is even possible that the amplitude of that variability could increase. For biota, extreme events associated with this variability might be at least as influential as any long-term trend. For the Labrador Shelf and Northeast Newfoundland Shelf, it is probably at least as important to know how the North Atlantic Oscillation will behave (especially the intensity and location of the Icelandic Low) as it is to know that global temperature will rise.

In the absence of region-specific information on likely future developments of climate, all predictions of climate-driven changes in the marine ecosystem off Newfoundland and Labrador can only be highly tentative. The following subsections describe the changes that seem most likely under three different scenarios: no change or even cooling of climate, moderate warming, and considerable warming.

13.4.4.1. No change

As temperatures were generally below the long-term average during the ACIA baseline period (1981–2000), no change from present conditions or even a cooling are likely to favor the current balance of species in the system. This implies a predominance of commercial invertebrates like northern shrimp and snow crab and cold water species of fish such as Greenland halibut, polar cod, and capelin.

13.4.4.2. Moderate warming

The moderate warming scenario (an increase of 1 to 3 ºC) assumes that there will be a gradual warming of the shelf waters off Labrador and Newfoundland. Using the events in West Greenland during the first half of the 20th century (Vilhjálmsson, 1997) as a spatial/temporal analogue, there is likely to be better recruitment success and northward expansion of Atlantic cod and some other demersal fish that live mainly on the shelf. Capelin is also likely to shift northward. If zooplankton abundance is enhanced by warmer water, capelin growth is likely to improve. It is possible that many existing capelin spawning

beaches will disappear with the projected rise in sea level (Shaw et al., 1998). Depending on the increase in sea level, storm events, and the availability of glacial deposits, some beaches may move and new beaches be formed, while others may disappear completely. While beach-spawning capelin can adapt to spawning on suitable sediment in deeper water, survival of eggs and larvae appears to be adversely affected (Nakashima and Wheeler, 2002), suggesting that a rise in sea level is likely to result in reduced survival and recruitment for capelin. A warming of sea temperatures is likely to retard recruitment to snow crab and northern shrimp, so these species might experience gradual reductions in productivity. Thus, a gradual, moderate warming of sea temperature is likely to promote a change back to a cod–capelin system from the present system where snow crabs and northern shrimp are the major commercial species. In addition, both cod and capelin are also likely to become more prominent off central Labrador than they were during the 1980s.

A gradual warming of shelf waters is also likely to promote a shift of more southerly species into the area. For example, haddock is likely to become more abundant on the southern part of Grand Bank, and expand into the study area. Migrants from the south, such as short-finned squid, mackerel, and bluefin tuna, are likely to occur more regularly and in greater quantities than in the 1980s and early 1990s.

The simple scenario of a gradual change back to a cod–capelin system under moderate warming conditions is uncertain. This is because the influence of oceanographic variability in the past is still not clear, and because it is likely that the dynamics of some species are now dominated by a different suite of factors than was the case in the past. It is highly likely that the ecosystem off northeastern Canada changed substantially as a consequence of fishing during the first four centuries after the arrival of European fishers, changed even further with the increasingly intensive fishing of the 20th century, and has changed dramatically from the 1960s onward. The magnitude of these changes is such that it would be difficult to predict accurately the future state of this ecosystem even without the added complications of climate change. Thus, the system could remain in its current state, could revert to some semblance of an historic state (or at least the state of the early 1980s), or could evolve toward something previously unseen.

Changes in sea ice (see Tables 9.2 and 9.3) are likely to have a negative impact on harp seals, the most important marine mammal predator in the area. Sea-ice duration is projected to shorten and it is not known whether harp seals would be able to adjust their breeding time to accommodate this change. A decrease in sea-ice extent is unlikely to affect harp seals because they would probably shift their distribution with the sea ice. However, thinner sea ice may be deleterious, resulting in increased pup mortality. Increases in regional storm intensities (see Table 9.1) are likely to result in higher

pup mortalities if such storms occur during the critical period shortly after birth (G. Stenson, Fisheries and Oceans Canada, St. John's, pers. comm., 2003). Changes in seal abundance are likely to cascade through the ecosystem, since seals are important predators on many fodder fish and commercially important ground-fish (Bundy et al., 2000; Hammill and Stenson, 2000), and are thought by some to be important in impeding the recovery of cod (DFO, 2003a) and thus maintaining the present balance within the ecosystem.

In addition to uncertainty regarding the response of individual species and the ecosystem as a whole, there is uncertainty regarding the influence of changing sea-ice cover on the fisheries themselves. A reduction in the extent and duration of sea ice may permit fishing further to the north and would increase the period during which ships would have access to certain fishing grounds. In particular, these changes in sea-ice cover would affect the Greenland halibut and shrimp fisheries in Baffin Bay and Davis Strait. For example, an increased open water season and extended fishing period is thought to have the potential to increase the harvest of Greenland halibut at the time of spawning (late winter/spring).

A reduction in sea-ice cover (see Tables 9.2 and 9.3) is also likely to negatively impact upon Greenland halibut fisheries that are conducted through fast ice. For example, a fishery that was developed in Cumberland Sound on Baffin Island in the late 1980s has developed into a locally important enterprise (Crawford, 1992; Pike, 1994). The fishery is conducted with longlines set through ice over deep (600–1125 m) water, with the season extending in some years from mid-January to June. Since the mid-1990s, the season has been shorter, typically from early February to May (M.A. Treble, Fisheries and Oceans Canada, Winnipeg, pers. comm., 2003). To date, attempts at fishing during the open water season have not proved successful. The catches have been small and the fish appear dispersed. It is unclear whether the fish would be present in commercial concentrations in the winter/spring if sea ice were not present. Even if they were, the absence of sea ice would certainly affect the conduct of the fishery.

13.4.4.3. Considerable warming

Since a warming of 4 to 7 °C is beyond any recorded experience in the Newfoundland–Labrador area, a meaningful discussion of the considerable warming scenario is not practicable. In very general terms, such a shift could favor cold-temperate species such as cod, improve conditions for more southern species such as haddock and herring, and even lead to the formation of demersally spawning stocks of capelin in addition to beach spawning stocks. However, there are likely to be other changes, such as a freshening of the surface layer due to freshwater from melting sea ice further north, which would be likely to reduce primary production in the area.

13.4.5. The economic and social importance of fisheries

From an economy based primarily on the fishery, Newfoundland has, along with most of North America, moved to a service economy. By 1971, for instance, the fishing and fish processing sectors accounted for less than 5% of Newfoundland's GDP, whereas the service sector accounted for more than half. Mining accounted for 11% and construction 18% (although that included construction of some of the large diversification projects). Nearly twenty years later, in 1989, shortly before the groundfish collapse, the fishery harvesting and processing sectors together accounted for slightly more than 5%, service industries had grown to 68%, mining had fallen to less than 6%, and construction to 8% (for a more extensive discussion see Schrank et al., 1992). By 2001, the fishery harvesting and processing sectors accounted for only 3% of GDP, the service industries remained constant at 68%, construction had slipped to 4.7%, and conventional mining to 3%. Oil production, a new industry in Newfoundland, already accounted for 8.4% of the provincial GDP, with every prospect of growing (the 2001 data were from the Newfoundland Statistics Agency; www.nfstats.gov.nf.ca/statistics/GDP/GDP_Industry.asp). Mining was also expected to see resurgence with the potential opening of a large nickel mine in Labrador.

While the fishery may not be of great importance to the overall Newfoundland economy, it continues to dominate completely the economy in rural areas, and perhaps even more importantly, its culture. After fifty years, there is still a daily *Fisheries Broadcast* on radio and when the Canadian Broadcasting Company decided to cancel the weekly television program *Land and Sea*, which often focuses on the fishery, public pressure forced the crown corporation to continue the program. With the fishery in deep trouble in 1989, the dominant newspaper in the province, *The Evening Telegram*, commented in an editorial entitled "Too Many Fishermen?" on 1 June 1989, that "Newfoundland's fishery must eventually be expanded and diversified so that it can employ more people, not fewer…"

With the spectacular change in fisheries employment that accompanied the collapse of the northern cod stock, there has been a sharp reemphasis on economic diversification. The two areas paraded as holding the hope of the future are tourism and information technology (Government of Newfoundland and Labrador, 2001). Progress has been made in both areas (e.g., fishing vessels converted to tour boats for whale watching, and many bed and breakfast establishments), but has been uneven, and some government policies have been inconsistent with the promotion of these industries. For instance, despite its interest in developing tourism, the Newfoundland government decommissioned or privatized a substantial number of the parks in the province's extensive parks system (Overton, 2001). How many of those sold remain as parks is unknown.

The real problem with the emphasis on tourism and information technology is that it is happening at the time as it is happening throughout the world. Why should Newfoundland have an advantage over the rest of the world in either field? It is too early to tell whether this diversification will be successful.

The story of the Newfoundland fishery does not end with the collapse of the groundfishery, its catastrophic consequences for many families, and the serious pressures it placed on the government. Two critical sets of changes have occurred since 1992: (1) the fishery management process has evolved and (2) shellfish have replaced groundfish as the main components of fishery landings in Newfoundland.

Fishery management by restricting total allowable catches began in Newfoundland in the mid-1970s. Following a particularly dramatic race to the fish in 1981, the government imposed, at the industry's request, enterprise allocations on the offshore groundfish fleet in 1982. These allocations were divisible and transferable in the year in which they were assigned. Government emphasized that these were rights to fish as opposed to property rights, which could be permanently sold. By this time, gear and geographic restrictions had been imposed, as had limited entry to non-groundfish inshore fisheries. With the expansion of the crab fishery, enterprise allocations have also been assigned to this inshore sector. These allocations are not transferable. The federal government has relinquished the licensing of fishers in favor of the provincial Professional Fish Harvester's Certification Board. This board was established as part of a professionalization program and it licenses harvesters either as apprentices or in one of two professional classes. The federal government, in turn, in 1996 established "core" fishing enterprises for the inshore fisheries. Senior level professional fishers who met certain conditions were declared the heads of core fishing enterprises. Approximately 5500 of these were established and the government claimed that no additional core licenses would be issued; the only way that fishers could obtain such status would be to buy out the core license of an existing core fisher. In an attempt to reduce the number of fishers, the federal government bought approximately 1500 core licenses, claiming that these will not be reissued. The final major changes in the management system are that (1) species license fees (access fees) are no longer nominal, for most important species they are based on the anticipated gross income from the fishery; and (2) there is now an extensive system of public consultations before recommendations concerning total allowable catches are made to the Minister of Fisheries and Oceans. For a discussion of the current fishery management system, see Schrank and Skoda (2003).

The value of landings in all Newfoundland fisheries in 1991 was Can$ 282 838 000. This fell during the first year of the moratorium to Can$ 194 745 000 and then doubled to Can$ 388 700 000 by 2000. Viewed alternatively, the period of the northern cod moratorium saw

an increase of one-third in the real value of Newfoundland fish and shellfish landings. But, while in 1991 43% of the value of landings was for cod, in 2000 46% was accounted for by crab and a further 30% by shrimp. With some cod stocks reopened on a limited basis for commercial fishing, cod accounted for 9% of the total landings in 2000, although this had earlier (in 1996) fallen to less than one-half of one percent (www.dfo-mpo.gc.ca/communic/statistics/landings).

For environmental reasons, whether the lack of predation or favorable climatic conditions, the shellfish population has surged and there has been a nearly complete conversion of Newfoundland's fishing industry from groundfish to shellfish. The conversion took years to occur. Labor requirements for shellfish are lower than for groundfish and, having higher unit prices, the shellfish quantities that yield these landings figures are much smaller than for groundfish.

Since all major species are under quota, total allowable catches for shrimp and crab have been increasing rapidly, along with the number of harvesting and processing licenses for shrimp and crab. The number of shrimp harvesting licenses rose from 19 in 1986 and 57 in 1991 to 438 in 2000. The numbers of crab licenses for those years were 274, 721, and 3333 (Corbett, 2002). There has been much controversy as to whether the old error of issuing too many licenses has occurred for crab. Even with the exodus from the province, in February 2003 there was still a 17.5% seasonally adjusted unemployment rate in the province (where the national figure was 7.4%) with continued pressure to open closed plants and increase licenses for crab fishers. While the number of crab fishing licenses has increased substantially, the increase in the number of crab processing plants has been modest.

13.4.6. Past variations in the fishing industry and their economic and social impacts

The *Evening Telegram* editorial, referred to in section 13.4.5, appeared within the context of a fishery that had long been in trouble. In 1967, a provincially financed report supported the trend away from a seasonal inshore fishery in Newfoundland toward a capital-intensive year-round offshore fishery. The report also noted that the "number of people dependent on the fishery should be reduced" (Pushie, 1967, 185). This has been a recurring theme. In 1970, the federal fisheries department appealed to the Canadian cabinet to permit the department to establish regulations that would lead to a 50% reduction in the number of Atlantic Canadian (meaning mainly Newfoundland) fishers.

The authority to effect these changes was denied (Schrank, 1995). The fishery faced repeated crises, was repeatedly studied, and the conclusion was repeatedly drawn that too many people were dependent on it. One study estimated that of the then 35 000 licensed fishers, only 6000 could be supported unsubsidized by the fish-

ery at a better than poverty-level income. The same study concluded that for every dollar of fish landed, there was a dollar of subsidy (Schrank et al., 1986). In 1976, with the extension of coastal states' fishery jurisdiction to 200 nm from shore, the two Canadian departments concerned (fisheries and regional economic expansion) both published reports stating that there was sufficient extra capacity in the industry that no significant employment benefits could be expected from the expanded jurisdiction (Government of Canada, 1976a,b). Two years later, a provincial government report made a similar point by stating that the Canadianized fishery, when fully developed, could employ only 9000 inshore fishers (Government of Newfoundland and Labrador, 1978). Yet, in response to popular pressure, both federal departments, as well as the provincial government, licensed and subsidized a tremendous expansion in the physical capacity of the industry: from 13 636 registered fishers in 1975 to 33 640 in 1980; from 9517 registered inshore vessels in 1976 to 19 594 in 1980; from a fish freezing capacity of 181 000 t in 1974 to 467 000 t in 1980; from net fishers's unemployment insurance benefits of US$ 30 724 000 in 1976/77 to US$ 66 060 000 in 1980/81; and from outstanding loans of the provincial Fisheries Loan Board (to finance inshore vessels) from US$ 36 869 000 in 1976/77 to US$ 78 558 000 in 1980/81 (Schrank, 1995). By 1981 the expansion had stopped and the two federal departments agreed that no further expansion of fish processing facilities would be built with federal financing (LeBlanc and De Bané, 1981). However, the damage had already occurred and, in the face of the anti-inflation recession of the early 1980s in the United States (where most of the Newfoundland fish production was sold), the market for Newfoundland fish products shrank dramatically and most Newfoundland fish processing companies faced bankruptcy.

As a result, the industry was financially, but not structurally, reorganized and the massive industrial closures implicit in bankruptcy were averted (Kirby, 1982). Yet, starting in 1982, inshore groundfish catches fell and after 1986 offshore catches followed. By 1992, the situation was so bad that a moratorium on the commercial catching of the formerly massive northern cod stock was put into place. Shortly after, nearly all Newfoundland groundfisheries were closed and the moratorium was extended to non-commercial fishing (Schrank, 1995). The closure of most of these groundfisheries continues, in whole or in part, to the present. The closure of the Newfoundland groundfisheries is reputed to have involved the largest mass layoff of labor in Canadian history. In social terms (due to the mass layoff), in biological terms (due to the decimation of the fish stock), and in governmental financial terms (due to billions of dollars spent on income maintenance for fishers and fish plant workers) the moratoria were disasters.

The response of government, industry, and the public to the moratoria indicates what might happen with climate change. Although the cause of the stock destruction in Newfoundland waters may be debated, the dramatic effect on the fish population is incontrovertible. Should significant changes in environmental conditions occur, and should these changes have substantial effects on commercial fish stocks, then the Newfoundland experience may provide a template for what might be expected to happen elsewhere. Moreover, the Newfoundland experience may also indicate the need for alternative policies.

The decline in the cod fisheries was better understood after the reports by Alverson (1987) and Harris L. (1989, 1990). That major problems were developing in the groundfishery was no longer debatable. In 1990, in response to the decline of the fishery, the federal government introduced the Atlantic Fisheries Adjustment Program (AFAP; see Schrank, 1997). The emphasis was on the word "adjustment". People were to be retired from the fishery, rural communities were to receive money to help them diversify their economies away from the fishery, and steps were to be taken to increase scientific understanding of the declining fish stocks. But only a few hundred fishers left the industry. With the shock of the total closure of the commercial northern cod fishery in July 1992, the federal government, anticipating that the fishery would revive in two years, created the Northern Cod Adjustment and Recovery Program (NCARP; see Schrank, 1997). Again there was an emphasis on people adjusting out of the fishery. This program called for early retirement of fishers, buybacks of fishing licenses, training of fishers for other trades, and income maintenance payments to fishers and fish plant workers. A third of the 9000 northern cod fishers and half the 10 000 plant workers affected by the northern cod shutdown were expected to leave the fishery. In fact, only 1436 took early retirement and 876 fishers sold their licenses. Fishers were not convinced that the shutdown would continue for long, and believed that the government would support them until the fishery reopened; the relatively uneducated, potential low end laborers did not see a need to leave an industry in which they were skilled and for which they were trained from an early age. One reason for low educational levels (until 1991, less than half Newfoundland's adult population had completed high school) was the fishing tradition. Boys started fishing with their fathers at a young age and looked forward to leaving school as soon as possible to join the family fishing enterprise. Boys and girls with little interest in fish harvesting could work for life in the local fish plant, in jobs which mostly required little formal education.

However, the fish did not return after two years, and have still not returned a decade after the start of the moratorium. As NCARP was ending, a new adjustment program began. The Atlantic Groundfish Strategy (TAGS; see Schrank, 1997) was to be a five-year program of income maintenance and adjustment (license buybacks and retirements) in which a 50% reduction in fishing capacity was anticipated. Again, there was very little movement of people out of the fishery. Their reluc-

tance to abandon the fishery was for the same reasons as under the NCARP program.

As TAGS drew to a close at the end of the 1990s, the government took a harder line. The post-TAGS program did not resemble its predecessors: income maintenance was severely cut and many people were removed from the program. With government financial support gone, or going, and the fish still not returned, an exodus from the fishery finally occurred.

Between 1986 and 1991, the Newfoundland population stagnated, at least partially from a dramatic drop in family size. From the highest birth rate of Canadian provinces, by 1991 Newfoundland had the lowest. Also, there had always been modest migration out of the province. But in the five years between 1991 and 1996 (from the year after the start of AFAP to halfway through TAGS) the population actually fell by 3%. With the continuing moratorium and the change in government policy, the exodus increased significantly and between 1996 and 2001 there was a further drop of 7%. Census figures for 2001 are from Statistics Canada (2002a), while those for 1991 and 1996 are from Statistics Canada (1999).

Even though such a population drop in a province over a decade is dramatic, this value of 10% actually hides the severity of the impact of the fishery collapse on Newfoundland's rural communities. Trepassey, on the southern shore of the Avalon Peninsula, was the location of a major groundfish processing plant. Newfoundland groundfish operators had been operating under an Enterprise Allocation scheme since 1982. With the drop in fish stocks toward the end of the 1980s, enterprise allocations were cut and, in response, a number of fish plants closed. One of the first to close, in 1990, was that in Trepassey. The result was that a town with 1375 inhabitants in 1991 had shrunk by more than 35% to 889 in 2001. Many rural communities in Newfoundland have seen population declines since 1990 of 15 to 30% (Statistics Canada, 2002b).

13.4.7. Economic and social impacts of climate change: possible scenarios

Climate change is likely to cause changes in the size of fish stocks. The effects are unlikely to be greater than the historical changes described in section 13.4.6. With human society, responses to impulses are not "natural" in the sense that a climatic change "causes" a human response. The human response is determined by the magnitude of the stimulus plus the political response of the society. In this sense, societal responses to climate change will not be qualitatively different from society's responses to past changes. The political system will respond, and the details of that response are impossible to predict. But models exist from past experience. However, many of the federal and provincial interventions in the fishery since 1992 have appeared ill thought out, often unfair, and have raised controversy.

A recent case provides an illustration. The groundfish plant in Twillingate was once owned by the largest fish company in Newfoundland, Fishery Products International, Ltd., but had been sold to another operator in the mid-1980s (Schrank et al., 1995). With the northern cod moratorium in 1992, the plant was shut and remained shut until 2002 when it opened as a shellfish plant with more technologically sophisticated equipment than had been used for groundfish. The Marine Institute, a branch of Memorial University, introduced a course to teach fish plant workers to use the new equipment, charging more than CAN$ 400 per person. For unemployed people receiving (un)employment insurance the fee was paid by the federal government. Others had to pay for themselves. Most unemployed people without employment insurance could not afford the fee. Most working people, wanting higher paying jobs in the fish plant, or former fish plant workers wanting to return to the industry, would need to quit their jobs to take the course, unless they were granted time off, which is unlikely in unskilled trades. But if they quit their jobs and completed the course, there was no guarantee of a job in the Twillingate, or any other technologically advanced, fish plant (CBC, 2002). Thus, every aspect of the long adjustment process which started with the decline of the groundfishery in the 1980s has been characterized by a deep sense of unfairness.

The Newfoundland experience shows that a "catastrophic" event concerning the fishery leads to severe adjustment problems, and that the adjustment period may be very long, but that it also raises new potential for a successful industry. The issues seem to be:

- how to convince participants in the industry that there is a crisis;
- adjustments that need to be made;
- the role of government; and
- how to protect the new fishery from the mistakes of the failed fishery.

In terms of predicting the socio-economic effects of long-term climate change, this is one case where it is easier to prescribe than to predict. The Newfoundland experience has shown reactions to expanding fish populations and to shrinking fish populations. In neither case was the reaction, in terms of government action or political pressure, appropriate. During the expansion period of the late 1970s, the fishery expanded too much, with excessive and ultimately largely immobile labor and capital entering the industry. Whereas a properly managed fishery would have restricted the expansion of production factors, the expansion was almost without letup until stopped by a general economic crisis. It was understood at the time that employment expansion was an incorrect response. Should fish stocks off Newfoundland increase over the next 20 or 50 years, care should be taken (1) to restrict by government regulation the magnitude of any expansion of capital and labor in the fishery; or (2) to ensure that such economic incentives are in place that excessive growth does not occur; or (3) to combine the two.

Should fish stocks decrease over the next 20 or 50 years, then it should be clear from the start that endless subsidies will not be forthcoming. License buyouts, even generous license buyouts of core enterprises for instance, would help. While these payments are subsidies, they are limited in scope and time and would have the effect of permanently shrinking the factor base of the industry. In the 1990s, such a policy would have been much cheaper and much less stressful for the fishing families affected, than the offering of income maintenance payments.

A gradual warming of shelf waters is likely to lead to increased opportunity for aquaculture. Warmer temperatures and shorter periods of sea-ice cover are likely to enable mussel farming to be more productive. Warmer waters are also likely to promote the development of Atlantic cod farming. If inshore waters become sufficiently warm, it is likely to be possible to farm Atlantic salmon along the east coast of Newfoundland. This is presently impossible because water temperature in winter falls below the lethal temperature for salmon.

13.4.8. Ability to cope with change

Climate change will affect all aspects of the fishery: the range of existing species, the relative populations of different species, and the economic circumstances of people who depend on the fishery for a living. How ready the economic and social systems of Newfoundland are to cope with these changes is not clear. When the Newfoundland fishery was revitalized after the declaration of the 200 nm limit, its economic structure over-expanded with largely immobile capital and labor and resulted in disaster. When the cod fishery started to decline in the late 1980s, several years passed before many of the necessary adjustments occurred. Whether the situation will be any different in response to climate change depends on whether lessons have been learned, and whether the social and political systems are prepared to adjust. Both the expansion of the ground-fishery in the late 1970s and the failure of the fishery to adjust to decimated stocks in the early and mid-1990s were largely due to the subsidies. During the 1970s the expansion was mainly financed by the federal and provincial governments. Despite the efforts of the federal government to adjust fishers out of the industry in the 1990s, the adjustment programs became income maintenance programs, which in effect encouraged fishers to remain in the industry in the hope that the fish would return. It was only when the subsidies were substantially reduced after 1998 that a significant number of fishers left the industry (based on the assumption that departures from the fishery are reflected in the census figures).

Subsidies are not the results of whimsical acts of governments or politics but are responses to real social and economic concerns. As long as the government considers the survival of small rural communities a major priority, subsidies to the fishery (the primary industry in these communities) will continue. While subsidies exist, the response of people to changes in the industry will be slow. Without subsidies, economic forces will require change, probably rapid change if the fishery is declining. If the biological base of the fishery is expanding, there is always the possibility that the industry will overexpand without government help. Government financial assistance would virtually ensure that overexpansion would occur.

To the extent that adjustments induced by climate change cause human suffering, the government can be expected to ameliorate the situation and ease the necessary transitions. But there is strong precedent for transition programs being transformed into short-run income maintenance programs. If that were to happen again, the process of adjustment is likely to be as long, painful, and wasteful as before.

Thus, it is impossible to predict how ready society is to cope with the effects of climate change. The response mechanisms are not automatic and political reactions will play a major role.

13.4.9. Concluding comments

The ecosystem off the northeast coast of Canada is under the influence of the Labrador Current, which carries cold water south from Davis Strait, the Canadian Archipelago, and Hudson Bay. As a result, climate impacts in this ecosystem can be compared to impacts on comparable ecosystems in the Northeast Atlantic and Iceland. Historically, the dominant demersal species were cod, Greenland halibut, and American plaice, the dominant invertebrates were northern shrimp and snow crabs, the dominant pelagic fish was capelin, and the dominant top predators were harp seals and whales.

The Labrador/Newfoundland ecosystem experienced major changes in the 1980s and 1990s. Atlantic cod and most other demersal fish, including species that were not targeted by commercial fishing, had declined to very low levels by the early 1990s. In contrast, snow crab and especially northern shrimp surged during the 1980s and 1990s and now support the most important fisheries in the area. Harp seals increased in abundance between the early 1970s and the mid-1990s. Capelin have been found in much reduced quantities in offshore acoustic surveys since the early 1990s, but indices of capelin abundance in the inshore surveys have not experienced similar declines, leaving the status of capelin uncertain and controversial.

The relative importance of overfishing and the environment on changes in cod and Greenland halibut has not been determined, although fishing is generally accepted as the most important factor affecting cod abundance. Ocean climate is thought to have had an impact on the lack of cod recovery, although this has not been quantified. Exploitation has not been shown to have affected any aspect of capelin biology in this area. Although there

have been several changes in capelin biology since the early 1990s, there is no clear indication of what external factor(s) has (have) influenced the changes. A combination of reduced predation and favorable environmental conditions probably contributed to the success of northern shrimp and snow crab. Harp seals increased because of reduced commercial harvesting.

Changes of the magnitude that have occurred in the biological components of the ecosystem since the early 1980s are unprecedented and together with the lack of regional predictions of changes in the ocean due to climate change, make predictions of biological responses to climate change highly speculative.

If there is no change from the present state or even a cooling, it is likely that the current balance of species will persist.

With a moderate, gradual warming, there is likely to be a change back to a cod–capelin system with a gradual decline in northern shrimp and snow crab. Cod and other demersal, shelf-dwelling species and capelin are likely to move north. Many existing capelin spawning beaches are likely to disappear as sea levels rise. If there is an increase in demersal spawning by capelin in the absence of new spawning beaches, capelin survival is likely to decline. Seals are likely to experience higher pup mortality as sea ice thins. Increases in regional storm intensities are also likely to result in higher pup mortality. A reduction in the extent and duration of sea ice is likely to permit fishing further to the north. A reduction in sea-ice cover is likely to shorten Greenland halibut fisheries that are conducted through fast ice.

If a more intense regional warming occurs as a consequence of extensive climatic warming, then predicting the responses of the biological community to these changes must occur in the absence of historic precedence and be completely speculative. Such an event is likely to improve conditions for cold-temperate species such as cod, improve conditions for more southern species such as haddock and herring, and even result in the formation of demersally spawning stocks of capelin.

Although the fishery in Newfoundland has accounted for 5% or less of provincial GDP since 1971, it dominates the economy and culture in rural areas. The cod fishery expanded rapidly in the 1980s and then contracted rapidly in the 1990s, the latter in response to the fishing moratorium. The social and economic effects of changes in fish stocks due to climate change are likely to be less than the historical changes experienced in the latter part of the 20th century in Newfoundland and Labrador.

Past experience suggests that the political system will respond but that the details of the response are impossible to predict. It is, however, possible to prescribe directions that governments should follow in the event of expansions or contractions of fish stocks resulting from climate change. If fish stocks off Newfoundland increase over the next 20 or 50 years, care should be taken (1) to restrict by government regulation the magnitude of any expansion of capital and labor in the fishery; (2) to ensure that such economic incentives are in place that excessive growth does not occur; or (3) to combine the two. If fish stocks decrease over the next 20 or 50 years, then it should be clear from the start that endless subsidies will not be forthcoming. License buyouts, even generous license buyouts of core enterprises for instance, would help. While these payments are subsidies, they are limited in scope and time and would have the effect of permanently shrinking the factor base of the industry.

Aquaculture in Newfoundland and Labrador is relatively small but there is interest in expansion, especially with the lack of recovery of cod stocks. A gradual warming of shelf waters is likely to lead to increased opportunity for aquaculture. Warmer temperatures and shorter periods of sea-ice cover are likely to enable mussel farming to be more productive. Warmer waters are also likely to promote the development of Atlantic cod farming and the farming of Atlantic salmon along the east coast of Newfoundland.

13.5. North Pacific – Bering Sea

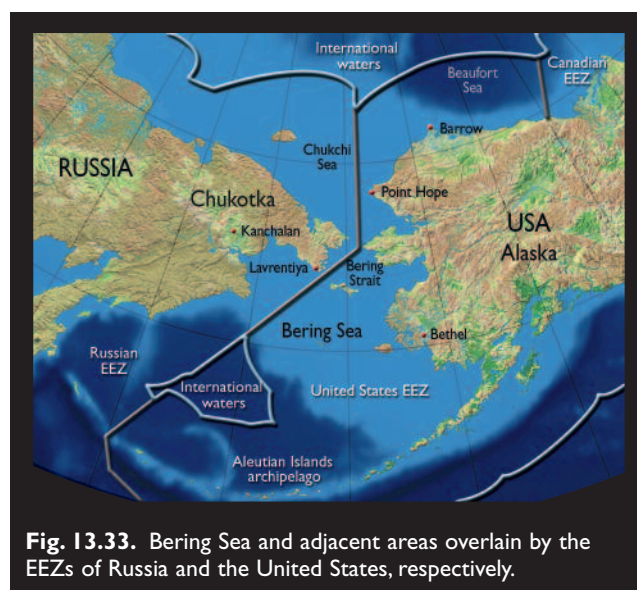
The continental shelves of the eastern and western Bering Sea together produce one of the world's largest and most productive fishing areas (Fig. 13.33). They contain some of the largest populations of marine mammals, birds, crabs, and groundfish in the world (Overland, 1981). A quarter of the total global yield of fish came from here in the 1970s. The central Bering Sea contains a deep basin that separates the shelves on the Russian and American sides and falls partly outside the 200 nm EEZs of the two countries. Prior to extended fishing zones, a complex set of bi- and multilateral fisheries agreements was established for the area. These range from agreements on northern fur seal (*Callorhinus ursinus*) harvests and Canada/US fisheries for Pacific salmon (*Oncorhynchus* spp.) and Pacific halibut (*Hippoglossus stenolepis*), to the multilateral International


Fig. 13.33. Bering Sea and adjacent areas overlain by the EEZs of Russia and the United States, respectively.

North Pacific Fisheries Convention for the development and use of scientific information for managing fisheries on the high seas (Miles et al., 1982a,b). (Various post-EEZ license agreements have permitted fishing by non-Russian and US fleets. At present such fishing is precluded in the US EEZ and is much reduced in waters of the Russian Federation.) In the so-called "Donut Hole", a pocket of high seas area surrounded by US and Russian EEZs, scientific research and commercial fishing are carried out in accordance with the Convention on the Conservation and Management of Pollock Resources in the Central Bering Sea by the two coastal states and Japan, Korea, Poland, and China. The North Pacific Science Organization and the North Pacific Anadromous Fish Commission were established to facilitate fisheries and ecosystem research in the North Pacific region, including the Bering Sea.

Commercial fisheries in the Bering Sea are generally large-scale trawl fisheries for groundfish of which about 30% of the total catch is processed at sea and the rest delivered to shoreside processing plants in Russia and the United States. Home port for many of the Bering Sea vessels is outside the ACIA region reflecting the comparative advantage of supply and service available in lower cost regions. Small coastal communities have a strong complement of indigenous peoples with subsistence fishing interests. They depend on coastal species, especially salmon, herring, and halibut, but the overlap with commercial activities is generally small. Anadromous species extend far inland via the complex river systems and are critical resources for indigenous peoples. The chief indigenous involvement in the marine commercial sector is the Community Development Program in the Northeast Pacific where 10% of TACs are allocated to coastal communities and their chosen partners (Ginter, 1995). Because the eastern Bering Sea is within the EEZ of the United States, harvest levels of commercially important species of fish and invertebrates are regulated through federal laws. Management plans exist for the major target species that specify target fishing mortality levels calculated to maintain the long-term female spawning stock levels at 40% of the unfished equilibrium level for fully exploited species. In the western Bering Sea, within the Russian EEZ, fishery management is executed on the basis of an annual TAC established for all commercial stocks of fish, invertebrates, and marine mammals. Allowable catch is calculated as a percentage of the fishable stock. Percentages for individual stocks and species were based on early scientific studies and do not exhibit annual change. However, since 1997, these harvest percentages have been revised by government research institutes, using new modeling applications and adaptive management approaches. The recommended TACs are approved by the special federal agency and issued as a governmental decree.

Annual catches of all commercial groundfish species between 1990 and 2001 in the US eastern Bering Sea EEZ ranged from 1.3 to 1.8 million t and averaged 1.6 million t. The walleye pollock (*Theragra chalcogramma*)

catch averaged 1.2 million t and ranged from 0.99 to 1.45 million t (Hiatt et al., 2002). In the western Bering Sea, the total groundfish catch reached 1.45 million t in 1988 of which walleye pollock contributed 1.29 million t. The annual catch of walleye pollock between 1990 and 2001 averaged 0.73 million t ranging from 0.45 to 1.06 million t. Walleye pollock comprised 89% of the catch, on average, over the 11-year period.

Aquaculture is not a particularly important activity in the Bering Sea region. In the eastern Bering Sea region, Alaska has adopted policies that prohibit aquaculture but enable some land-based hatcheries that produce salmon for release into the sea to supplement at times of low escapement. Some of these salmon pass through the eastern Bering Sea and may have some effect on larvae, for example red king crab (*Paralithodes camtschaticus*) larvae, but this has not been demonstrated. None of the hatcheries operate in the western Bering Sea region (NPAFC, 2001).

13.5.1. Ecosystem essentials

The Bering Sea is a subpolar sea bounded by the Bering Strait to the north and the Aleutian Islands archipelago to the south (Fig. 13.33). Geographically, the Bering Sea lies between 52° and 66° N, and 162° E and 157° W. The narrow (85 km long) and shallow (<42 m deep) passage of the Bering Strait connects the Bering Sea to the more northern Chukchi Sea and the Arctic Ocean to the north. The sea area covers almost 3 million km^2 and is divided almost equally between a deep basin in the southwest and a large, extensive continental shelf in the east and north. The eastern continental shelf is 1200 km in length, exceeds 500 km in width at its narrowest point, and is the widest continental shelf outside the Arctic Ocean (Coachman, 1986). The shelf is a featureless plain that deepens gradually from its extensive shoreline to the shelf break at about 170 m depth. There are very limited commercial fisheries in the Chukchi Sea or the Arctic Ocean north of the Bering Strait due to a known lack of resources, operating difficulties, and distance from markets. Marine mammal populations are locally important for subsistence use.

13.5.2. Fish stocks and fisheries

This section describes the life history characteristics, distribution, and trends in abundance and fisheries for the main species which are or have been the subject of important fisheries or which are important as forage fish for such species. Catch records for the major groundfish species of the eastern and western Bering Sea are shown by species in Figs. 13.34 and 13.35 respectively.

13.5.2.1. Capelin

In the Bering Sea, adult capelin only occur near shore during the month surrounding the spawning run. In other months they occur far offshore. In the eastern Bering Sea capelin occur in the vicinity of the Pribilof

Islands and the continental shelf break; in the western Bering Sea they occur in the northern Anadyr Gulf and near the northwestern Kamchatka coast. The seasonal migration may be associated with the advancing and retreating sea-ice edge. In the eastern Bering Sea, sea ice retreats during summer. As a coldwater species, capelin may migrate in close association with the retreating ice edge resulting in the summer capelin bio-mass located in the northern Bering Sea, an area not covered by surveys and with very little commercial fish-ing. Capelin aggregations near the northwestern Kamchatka coast have a stable distribution over the warm season. It is reported that the biomass of capelin and smelt grows in periods of climatic transition, when the abundance of other common pelagic fish (walleye pollock and herring) are low in the western Bering Sea (Naumenko et al., 1990). Capelin biomass was estimat-ed at 200000 t on the western Bering Sea shelf between 1986 and 1990. Their biomass may be much larger on the expanded eastern shelf. Nevertheless, capelin are not commercially exploited in the Bering Sea. In Russia, some attempts were made to include capelin and polar cod in a commercial fishery in the mid-1990s. Capelin are a major component of the diets of marine mammals feeding along the ice edge in winter (Wespestad, 1987) and of seabirds in spring.

13.5.2.2. Greenland halibut

In the Bering Sea, Greenland halibut (commonly known as Greenland turbot) spend the first three or four years of life on the continental shelf after which they migrate to deep waters of the continental slope where they live as adults (Alton et al., 1988; Shuntov, 1970; Templeman, 1973). Although tagging studies show that they undergo feeding and spawning migra-tions in the North Atlantic Ocean, it is unknown to what extent this happens in the Bering Sea. A slow-growing and long-lived species, Greenland halibut reach over 100 cm in length and 20 years of age in the Bering Sea. Greenland halibut are a valuable commer-cial product and have been caught in trawling opera-tions and by longlines. Catches of Greenland halibut and arrowtooth flounder were reported together in

the 1960s; combined catches ranged from 10000 to 58000 t per year with an average annual catch of 33700 t. The Greenland halibut fishery intensified in the 1970s with catches of this species peaking between 1972 and 1976 at 63000 to 78000 t per year, primari-ly taken by distant-water trawl fleets from Japan. Catches declined after implementation of the Magnuson Fishery Conservation and Management Act (FCMA) in 1977, where the US fisheries jurisdiction was extended to 200 nm from the coast. However, catches were still relatively high in 1980 to 1983 with an annual range of 48000 to 57000 t. After that, trawl harvest declined steadily and averaged 8000 t between 1989 and 2000. This decline is mainly due to catch restrictions placed on the fishery because of declining recruitment and market conditions. In the western Bering Sea, Greenland halibut were lightly exploited due to low stock abundance before the FCMA took effect in the eastern Bering Sea. In 1978, a Greenland halibut fishery began on the northwestern continental slope, mostly by longlines. Annual harvest varied from 2010 to 6589 t between 1978 and 1990 with part of the harvest resulting from bycatch in the Pacific cod longline fishery. Since the early 1990s, Greenland hal-ibut stock abundance and catches have declined. Resource assessment surveys on the continental shelf in 1975 and between 1979 and 2002 showed that intermediate size Greenland halibut (40–55 cm) were present throughout the region from 50 to 200 m depth during the late 1970s and early 1980s (Alton et al., 1988). By 1985 and 1986 the distribution range had decreased such that Greenland halibut were only encountered in the area to the west and south of St. Matthew Island and at much reduced densities. Since then, fish of this size range have only been caught in small quantities in the northern part of the survey area. It is unknown whether environmental conditions in the late 1970s and early 1980s were favorable for strong recruitment of Greenland halibut and levels have since returned to more normal recruitment lev-els, or whether there has been reduced recruitment to

Fig. 13.34. Catch by species from the eastern Bering Sea, 1955–2002 (NPFMC, 2004).

Fig. 13.35. Catch by species from the western Bering Sea, 1965–2002 (1965–1993 data from Committee on the Bering Sea Ecosystem, 1996; 1994–2003 data from the TINRO-Center archive, Vladivostok, Russia).

this stock since the mid-1980s. However, stock assessment models suggest a declining population since 1985 (Ianelli at el., 2001). Greenland halibut are widely distributed in the western Bering Sea but are not abundant there. The most significant Greenland halibut aggregations occur on the outer continental shelf and slope along the Korjak coast (Borets, 1997; Novikov, 1974). Survey results indicate that Greenland halibut abundance was higher in the northern Bering Sea in the 1990s than in the 1980s. However, the total biomass and overall distribution of this flatfish decreased in the Bering Sea region as a whole.

13.5.2.3. Shrimp

Pandalid shrimp (primarily *Pandalus jordani*) are widely distributed along the outer third of the eastern continental shelf where they are consistently caught in resource assessment trawl catches in small numbers. Humpy shrimp (*P. goniurus*) are distributed throughout the northern Bering Sea shelf and the Anadyr Gulf, in contrast to northern shrimp (*P. borealis*), which are much less abundant. Northern shrimp were the first commercially exploited shrimp in the Bering Sea after aggregations were discovered on the outer shelf north of the Pribilof Islands in 1960 (Ivanov, 1970). This fishery was conducted by Japanese vessels and peaked at 31 600 t in 1963. After that the northern shrimp stock declined sharply and commercial fishing ceased after 1967. Since then there has been no fishery for pandalid shrimp in the Bering Sea. Humpy shrimp aggregations were discovered in the Anadyr Gulf in 1967. A large-scale Russian trawl fishery harvested humpy shrimp in the northern Bering Sea in late 1960s to 1970s until they too became less abundant. Individual trawl catches of Humpy shrimp reached 10 t per 15 minute haul in the Anadyr Gulf, which became the catch value record in the world shrimp fishery. Humpy shrimp biomass was estimated at 350 000 t in the Anadyr Gulf in 1975. The annual Russian harvest of humpy shrimp exceeded 11 200 t in 1978 (Ivanov, 2001) but then declined due to the lack of a market for small-sized shrimp. Other pandalid shrimp species were also caught as bycatch in the pursuit of other target species.

13.5.2.4. Polar cod

Polar cod are caught in small amounts in resource assessment surveys at the northernmost survey stations on the eastern Bering Sea shelf. The southern extent of their summer distribution is related to bottom water temperature where they have been found to range from 59° N in 1999 (coldest year) to 62° N in 1996 (warmest survey year on record, except 2003). Since polar cod are found at such high latitudes, little information is available on their life history characteristics in the eastern Bering Sea and they are not pursued as a commercial species due to their low abundance. In the northwestern Bering Sea and the Chukchi Sea, polar cod are distributed at depths from 15 to 251 m (Tuponogov, 2001). A local fishery on polar cod exist-

ed there during years of high abundance (1967–1970; see Tuponogov, 2001).

13.5.2.5. Crabs

Snow crab and Tanner crab (*Chionoecetes bairdi*) are distributed throughout the eastern Bering Sea shelf with the exception of the shallow waters of Bristol Bay (Otto, 1998). The abundance of commercial size males was estimated at 183.5 million crabs in 1988 (Stevens et al., 1993). The distribution extends beyond the study area to the north and west, and to a small extent into the Gulf of Alaska. Owing to the relatively narrow shelf area of the western Bering Sea, snow crab abundance is notably less there. In 1969 the number of commercial size males was estimated at 25 million crabs (Slizkin and Fedoseev, 1989). An intensive directed fishery began for snow crab in the Bering Sea in the 1980s. They were initially caught incidental to the pursuit of red king crab until 1964 when both Japan and Russia increased their effort for this species due to a bilateral agreement with the United States to limit king crab catches (Davis, 1982). The combined Japanese–Russian catch of snow and Tanner crab increased until 1970 to 22 844 t (ADF&G, 2002), after which quotas were established for these nations' fishing fleets and the catch was sharply reduced. The American pot fishery (non trawl) began shortly after and catches increased during the 1980s to a peak in 1991 at 172 588 t. Catches rapidly declined with stock decrease but increased again in the mid-1990s as the snow crab stock condition improved. Since 2000, the stock has again declined and the commercial fishery is presently operating under reduced quotas. The Tanner crab fishery has been closed since 1997 in the eastern Bering Sea (NPFMC, 2002). In the western Bering Sea, there was no commercial snow crab or Tanner crab fishery in 2000 and 2001. Only insignificant catches (250 t) were allowed during research surveys. The results indicated some improvement in stock condition and a small commercial fishery was allowed in 2002.

13.5.2.6. Pollock

Walleye pollock (hereafter referred to as pollock) is the most abundant species within the Bering Sea and is widely distributed throughout the North Pacific Ocean in temperate and subarctic waters (Shuntov et al., 1993; Wolotira et al., 1993). Pollock are a semi-demersal schooling fish, which become increasingly demersal with age. They are a relatively short-lived (natural mortality estimated at 0.3) and fast-growing fish, females usually become sexually mature at four years of age. The maximum recorded age is about 22 years. The stock structure of Bering Sea pollock is not well defined. In the US part of the Bering Sea, pollock are considered to form three stocks for management purposes: the eastern Bering Sea stock (which comprises pollock occurring on the eastern Bering Sea shelf from Unimak Pass and to the US–Russian Convention line), the Aleutian Islands Region stock

(which occurs within the Aleutian Islands shelf region from 170° W to the US–Russian Convention line), and the Central Bering Sea stock (known as the Bogoslof Island pollock, and which are thought be a mixture of pollock that migrate from the US and Russian shelves to the Aleutian Basin around the time of maturity). There are only two stocks in the Russian EEZ. Pollock currently support the largest fishery in US waters and comprise 75 to 80% of the annual catch in the eastern Bering Sea and around the Aleutian Islands. From 1954 to 1963, pollock were only harvested at low levels in the eastern Bering Sea. Directed foreign fisheries first began in 1964 after which catches increased rapidly during the late 1960s, and peaked in 1970 to 1975 when they ranged from 1.3 to 1.9 million t per year. Following a peak catch of 1.9 million t in 1972, catches were reduced through bilateral agreements with Japan and Russia. Since the US claim to extended jurisdiction in 1977, the annual average eastern Bering Sea pollock catch has been 1.2 million t, ranging from 0.9 million t in 1987 to nearly 1.5 million t (including the Bogoslof Islands area catch in 1990), while stock biomass has ranged from a low of 4 to 5 million t to highs of 10 to 12 million t (NPFMC, 2002). In 1980, US vessels began fishing for pollock and by 1987 were able to take 99% of the quota. Since 1988, only US vessels have been operating in this fishery and by 1991, the current domestic observer program for this fishery was fully operational. In the southwestern Bering Sea, the pollock fishery developed slowly during the mid-1960s stabilizing at 200 000 to 300 000 t in the latter half of the 1970s and the 1980s. After 1995, there was a reduction in harvest due to a decline in pollock stocks in the western Bering Sea. After that, the total pollock catch in the Russian EEZ was maintained by increasing fishing activity in the Navarin region between 1996 and 1999, and ranged from 596 000 to 753 000 t. The pollock catch subsequently declined in the northern region due to poor stock condition as well as to the application of precautionary approaches in pollock fishery management. The total pollock catch in the Russian EEZ declined from 1 327 000 t in 1988 to 393 180 t in 2000. Vessels of "third countries" began fishing in the mid-1980s in the international zone of the Bering Sea (commonly referred to as the "Donut Hole"). The Donut Hole is located in the deep water of the Aleutian Basin and is distinct from the customary areas of pollock fisheries, namely the continental shelves and slopes. Japanese scientists began reporting the presence of large quantities of pollock in the Aleutian Basin in the mid- to late 1970s, but large-scale fisheries did not begin until the mid-1980s. Thus, the Donut Hole catch was only 181 000 t in 1984, but grew rapidly and by 1987 exceeded the catch within the US Bering Sea EEZ. The outside-of-EEZ catch peaked in 1989 at 1.45 million t and then declined sharply. By 1991, the Donut Hole catch was 80% less than the peak value, with subsequent low catches in 1992 and 1993. A moratorium was enforced in 1993 and since then only minimal pollock catches have been harvested from the Aleutian Basin by resource assessment fisheries.

In response to continuing concerns over the possible impacts groundfish fisheries may have on rebuilding populations of Steller sea lions (listed as an endangered species after four decades of decline), changes have been made in regulations of the pollock fisheries in the eastern Bering Sea and at the Aleutian Islands. Pollock are important prey items for Steller sea lions and these changes were designed to reduce the possibility of competitive interaction of the fishery with Steller sea lions. For the fisheries, comparisons of seasonal fishery catch and pollock biomass distributions in the eastern Bering Sea led to the conclusion that the fishery had disproportionately high seasonal harvest rates within critical sea lion habitat which could lead to reduced sea lion prey densities. Consequently, management measures were designed to redistribute the fishery both temporally and spatially according to pollock biomass distributions (the underlying assumption being that the independently derived area-wide and annual exploitation rate for pollock would not reduce local prey densities for sea lions).

13.5.2.7. Pacific cod

Pacific cod are widely distributed from southern California to the Bering Sea, although the Bering Sea is the center of greatest abundance for this species. Tagging studies have shown that they migrate seasonally over large areas. In late winter, Pacific cod converge in large spawning concentrations over relatively small areas. Spawning takes place over a wide depth range (40–290 m) near the bottom. Eggs are demersal and adhesive. Estimates of natural mortality range from 0.29 to 0.99, while a value of 0.37 is used in the stock assessment model. Pacific cod have been found aged up to 19 years and females are estimated to reach 50% maturity at 5.7 years, corresponding to an average length of 67 cm. Pacific cod are the second largest Bering Sea groundfish fishery. Beginning in 1964, the Japanese trawl fishery for pollock expanded and cod became an important bycatch species and an occasional target species during pollock operations (in the early 1960s, a Japanese longline fishery harvested Bering Sea Pacific cod for the frozen fish market). By 1977, foreign catches of Pacific cod had consistently been in the 30 000 to 70 000 t range for a full decade (Thompson and Dorn, 2001). The foreign and joint venture sectors dominated catches through 1988, when a US domestic trawl fishery and several joint venture fisheries began operations. By 1989, the domestic sector was dominant and by 1991 the foreign and joint venture operations had been displaced entirely. Catches of Pacific cod since 1978 have ranged from 33 000 t in 1979 to 232 600 t in 1997 with an average of about 141 900 t. At present, the Pacific cod stock is exploited by a multiple-gear fishery, including trawl, longline, pot, and jig components (with the exception of 1992, the trawl catch was the largest component of the fishery (in terms of catch weight) between 1978 and 1996. Since 1997, the longline fleet has taken the greatest proportion of Pacific cod). Pacific cod were estimated

to be at low abundance levels in 1978 but experienced strong recruitment (age 3) in the early 1980s, which built the stock to high levels. The population biomass peaked at 2.5 million t in 1987 and then declined gradually to about half the peak value in 2001. In the western Bering Sea, the Russian cod fishery developed slowly and was mostly unsuccessful until the late 1960s. Several attempts were undertaken by Japanese and local fishermen in longline and trawl fisheries development in the 1920s and 1930s. Meanwhile, commercially significant Pacific cod concentrations were described by scientific expeditions. In particular, dense aggregations were found in the northwestern area in 1950 to 1952 near the Navarin Cape (Gordeev, 1954). This led to the organization of a special cod fishery expedition in 1968 (Vinnikov, 1996). Pacific cod harvest from this area ranged from 6500 to 24500 t in the first years, and peaked at 117650 t in 1986. In the 1990s, catches declined due to a restructuring of the fishery and, in recent years, from decreases in cod abundance in the North Pacific. Pacific cod biomass was estimated at 766000 t in 1989 (Vinnikov, 1996) and had declined to 172000 t by 2000.

13.5.2.8. Flatfish

The flatfish harvest and resource is much smaller in the southwestern Bering Sea with its relatively narrow shelf than in the eastern Bering Sea. A directed flatfish fishery began in the mid-1950s in the southwestern Bering Sea. This is a small-scale land-based fishery using Danish seines and, to a lesser extent, trawls. Yellowfin sole (*Limanda aspera*) comprise the main part of the flatfish harvest in the southwestern Bering Sea (72.7% of the predicted flatfish TAC for 2002 and about 74% in Danish seine catches in recent years) and its biomass is estimated at 78000 t on the southwestern shelf compared to 1.6 million t in the eastern Bering Sea. Maximum catches in the southwestern Bering Sea, 32000 and 20000 t respectively, were registered in 1958 and 1959. The situation changed dramatically in 1960 and 1961 when the flatfish harvest fell to its lowest ever values (100 to 160 t). The stock condition improved over the following decades. By the mid-1960s catches had stabilized at approximately 6000 t per year which continued through 1974, after which they declined until the early 1980s. During 1996 to 2002, the flatfish catch in the southwestern Bering Sea varied from 6000 to 13500 t. In terms of other flatfish species, Alaska plaice (*Pleuronectes quadrituberculatus*), rock sole (*Lepidopsetta bilineata*), and northern flathead sole (*Hippoglossoides robustus*) are the most important in the southwestern Bering Sea.

The abundance of yellowfin sole is low in the northwestern Bering Sea. The most important flatfish species is northern flathead sole, which accounts for about two-thirds of the total flatfish biomass, followed by Alaska plaice, and rock sole. A directed flatfish fishery did not begin in the northwestern region until the 1990s and never developed extensively. However, the flatfish bycatch sometimes reached significant levels and between 1965 and 1984 ranged from 2440 to 29140 t in the northwestern Bering Sea. The flatfish bycatch increased to 33460 t in 1985 and 39900 t in 1986, leveling off at 24000 to 29000 t over the next six years, and then declining to an average of 9700 t after 1993. A target flatfish fishery did not develop extensively, and the target catches remained less than the bycatch in the large cod and pollock fisheries.

In the eastern Bering Sea, yellowfin sole is distributed from British Columbia to the Chukchi Sea, into the western Bering Sea, and south along the Asian coast to about 35° N off the South Korean coast (Hart, 1973). In the Bering Sea, it is the most abundant flatfish species and is the target of the largest flatfish fishery in the United States. While also found in the Aleutian Islands region and the Gulf of Alaska, the center of abundance for this stock is on the eastern Bering Sea shelf. Adults are benthic and occupy separate winter and spring/summer spawning and feeding grounds. They overwinter near the shelf break at approximately 200 m depth and move into nearshore spawning areas as the shelf ice recedes (Nichol, 1997). Spawning is protracted and variable, beginning as early as May and continuing through August, occurring primarily in shallow water at depths less than 30 m (Wilderbuer et al., 1992). Eggs, larvae, and juveniles are pelagic and usually found in shallow areas. The estimated age at 50% maturity is 10.5 years with a length of about 29 cm (Nichol, 1994). The natural mortality rate is likely to be within the range 0.12 to 0.16, with a maximum recorded age of 33 years (Wilderbuer, 1997). Yellowfin sole have been caught with bottom trawls on the Bering Sea shelf every year since the fishery began in 1954. Between 1959 and 1962 yellowfin sole was overexploited by Japanese and Russian trawl fisheries when catches averaged 404000 t annually. As a result stock abundance declined. Catches also declined to an annual average of 117800 t between 1963 and 1971, declining further to an annual average of 50700 t between 1972 and 1977. The yield in this latter period was partially due to the discontinuation of the Russian fishery. In the early 1980s, catches increased peaking at over 227000 t in 1985. In the 1980s, there was a major transition in the characteristics of the fishery in the eastern Bering Sea. Before this, yellowfin sole were taken exclusively by non-US fisheries and these fisheries continued to dominate through 1984. However, US fisheries developed rapidly in the 1980s, and foreign fisheries were phased out. Since 1990, only domestic harvesting and processing has occurred. The 1997 catch of 181389 t was the largest since the fishery became completely domestic, but decreased to 101201 t in 1998. The 2000 catch totaled 83850 t and the 2001 catch was 63400 t. For many years in the 1990s the yellowfin sole fishery was constrained by closures in order to attain the bycatch limit of Pacific halibut allowed in the yellowfin sole directed fishery. Stock biomass has declined by 1 million t from the peak biomass observed in 1985 and was estimated at 1.6 million t in 2002.

13.5.2.9. Salmon

The Bering Sea is important habitat for many stocks comprising the five species of Pacific salmon during the ocean phase of their life history. Here, the various stocks intermingle from origins in Siberia, Alaska, the Aleutian Islands, Japan, Canada, and the US west coast. The earliest fisheries for salmon were probably indigenous subsistence fisheries in which salmon were captured returning to their native streams to spawn. During the 20th century there were three main fisheries for salmon in the Bering Sea: the Russian and Alaskan domestic fisheries, the Japanese high-seas gillnet and longline fishery, and the bycatch of salmon in the groundfish fisheries.

Salmon canneries first appeared on the Alaskan side of the Bering Sea in the late 1890s to process fish returning to Bristol Bay. It is reported that between 1894 and 1917 the Kvichak and Nushagak rivers flowing into Bristol Bay produced 10 million sockeye salmon (*Oncorhynchus nerka*) annually (Netboy, 1974). Purse seines and gill nets were the primary fishing gear in the early days of the fishery. Gill nets were hauled from the beach using horses, which were later replaced by engines, whereas the purse seine fishery started around 1915 with the advent of powered fishing craft. Purse seining continues to the present as the primary gear in a highly mobile fleet fishing near-shore, which assures the targeting of specific salmon stocks. Although all five species of Pacific salmon are present in Bristol Bay, sockeye salmon are the most abundant and have dominated the salmon catch for years. The Bristol Bay salmon catch for all species totaled 42 million fish in 1993, of which 41 million were sockeye salmon, the largest catch on record (fishery statistics from the Pacific salmon fishery on the western Bering Sea coast (eastern Kamchatka region) are available since 1906). On average, pink salmon (*O. gorbuscha*) contributed 73.8% of the Russian salmon catch in the western Bering Sea between 1952 and 1993, chum salmon (*O. keta*) 24.2%, sockeye salmon 1.3%, chinook salmon (*O. tshawytscha*) 0.6%, and coho salmon (*O. kisutch*) only 0.1% (Chigirinsky, 1994). Since 1989, the runs of pink salmon to the eastern Kamchatka coast have been in good condition in odd years. The historical highest catch totaled 83 640 t in 1999. The average pink salmon catch (38 390 t) for 1989 to 2001 is more than twice the average level of 15 996 t for 1952 to 1993 (Chigirinsky, 1994). Similarly, chum salmon catches were stable at 11 000 to 12 000 t in 2000 to 2001 compared to 5250 t for 1952 to 1993. The recent improved stock conditions coincide with new fishery regulations, which limit the chum salmon bycatch during the pink salmon fishery. The main sockeye salmon fishery in eastern Kamchatka results from the productive Kamchatka River, slightly south of the Bering Sea.

The Japanese high-seas gillnet and longline salmon fishery expanded into the Bering Sea in 1952 with three motherships and 57 catcher boats, which increased to 14 motherships and 407 catcher boats by 1956 (Netboy, 1974). (Motherships are large vessels to which catcher boats deliver their catches and where the fish are processed for human consumption or reduced to meal and oil, they also carry fuel and other provisions for the catcher fleet.) The peak catch of 116 200 t occurred in 1955 and annual catches ranged from 71 000 to 87 000 t between 1957 and 1977 (Harris C., 1989). Sockeye, chum, and pink salmon comprised 95% of the catch in this fishery, which ceased operations in 1983. The bycatch of salmon in the commercial groundfish fisheries is of less importance than for the directed fisheries, but still accounts for fishing mortality important to resource managers. Observer sampling of the groundfish fishery indicates that chinook salmon are more frequent in bottom trawls and the other species more frequent in the pelagic trawls (Queirolo et al., 1995). In the western Bering Sea, primarily chinook and chum salmon were present in the bottom trawl catches during research surveys in 1974 to 1991 (Radchenko and Glebov, 1998).

13.5.2.10. Marine mammals

The Bering Sea contains a rich and diverse assemblage of marine mammals, including north temperate, arctic and subarctic species. Twenty-six species from the orders Pinnipedia (sea lions, walrus, and seals), Cetacea (whales, dolphins, and porpoises), and Carnivora (sea otter), and polar bears are present at varying times of the year (Lowry and Frost, 1985). Some species are resident throughout the year (e.g., harbour seal, Steller sea lion, sea otter (*Enhydra lutris*), beluga whale (*Delphinapterus leucas*), and Dall's porpoise (*Phocoenoides dalli*)) while others migrate into the Bering Sea during the summer on feeding excursions. Arctic species including polar bears, walrus, ringed and bearded seals (*Erignathus barbatus*), and bowhead whales (*Balaena mysticetus*) mostly occur in the Bering Sea during autumn and winter and are associated with the presence of seasonal sea ice. Most of the marine mammal species are found over the continental shelf and in coastal areas, although five whale species reside in the deep/oceanic waters of the Bering Sea basin (Lowry et al., 1982).

Harvesting of marine mammals has occurred since at least 1790, the first year when northern fur seal harvests were recorded (Langer, 1980). The harvest peaked in the 1870s at over 100 000 animals and was at levels exceeding 40 000 males annually until 1985 when the northern fur seal commercial harvest was stopped and only subsistence hunting by Aleuts was allowed in the Pribilof Islands. In the Russian EEZ, fur seal hunting has seen many changes since the mid-1980s. Since 1987, the experimental hunting of "silver" fur seals (aged 3–4 months) has been conducted on the Commander Islands (Boltnev, 1996). The harvest rate was established at 60% from the average annual male abundance for 1987 to 1989. Actually, significantly less than 50% were killed, which has further decreased to

less than 30% since 1989. The number of animals killed decreased from 6700 in 1995 to 3000 in 1999 and 2180 in 2000. The declining harvest is related to the decline in the fur seal population and the negative effect of disturbance by hunters on seal reproduction. All fur seal hunting is presently restricted to Bering Island. Bachelor males aged from two to five years were hunted on Medny Island until the mid-1990s (2134 animals were killed in 1994) and this area was then closed to harvesting in 1995. Whaling spread to the Bering Sea in the mid-19th century when large numbers (2500 in 1853) of bowhead whales were taken (NMFS, 1999). This harvest continued for 50 years until the bowhead whale population became depleted. The current subsistence harvest totals 60 to 70 whales annually. Some species, such as humpback and grey whales (*Eschrictius robustus*), which are present in the Bering Sea in summer, were historically harvested during the winter near Hawaii and California and in waters off the Chukotski Peninsula (about 130 to 135 whales). Kenyon (1962) reported that Steller sea lions were very abundant in the Pribilof Islands when discovered in 1786, but were soon overhunted. After protective measures were taken, numbers grew from a few hundred in 1914 to about 6000 in 1960. The population has since declined to low numbers and has been the subject of extensive research to find the cause of the decline.

In the United States, stock assessment information on the 39 stocks of the 24 species of marine mammals in the Bering Sea are used to classify each stock as either strategic, non-strategic, or not available (Angliss et al., 2001). Strategic stocks are those considered threatened, endangered, or depleted under US law. The strategic stocks include: northern fur seal, sperm whale, humpback whale, fin whale, the North Pacific right whale (*Eubalaena japonica*), and the bowhead whale. Three Bering Sea stocks also have further designations: northern fur seals are designated as depleted under the Marine Mammal Protection Act, and the western stock of Steller sea lion is listed as endangered under the Endangered Species Act, as is the bowhead whale. Nine of the 39 marine mammal stocks are estimated to be increasing, five are stable, three are declining, and the status of the others is unknown. Subsistence harvest is allowed for three species: northern fur seals, beluga, and bowhead whales. In Russia, marine mammal populations are classified as commercial, non-commercial, or protected. Protected species include all whales and dolphins (with the exception of grey whales, whaled by indigenous people for subsistence), sea otter, and polar bear. Some commercial quota is established for beluga whales, but is not taken. Walrus, spotted seal (*Phoca largha*), ringed seal, and ribbon seal (*P. fasciata*) are hunted in the northwestern Bering Sea. However, their harvest has been relatively low since the cessation of ship-based hunting operations. In 1998 to 2000, the harvest was less than 60% of the established TAC on different seal species and averaged 32.8%.

13.5.3. Past climatic variations and their impact on commercial stocks

Climate change primarily influences ocean water temperatures through the regulation of synoptic atmospheric processes and water exchange between the western Bering Sea and the Pacific Ocean. Four physical processes determine the change in ocean climate regimes in the North Pacific (Schumacher, 2000): the lunar tidal cycle, variations in solar radiation (Davydov, 1972; Van Loon and Shea, 1999), changes in the North Pacific circulation that affect air–sea exchange of heat and, finally, changes in the momentum of the Aleutian Low atmospheric pressure pattern. These processes generate a subset of basin-scale factors, each of which contributes to the oceanographic conditions of the Bering Sea. The Aleutian Low is an example of an atmospheric activity center in the northern-hemisphere (Beamish and Bouillon, 1993; Francis et al., 1998; Hollowed and Wooster, 1992; Latif and Barnet, 1994; Luchin et al., 2002; Wooster and Hollowed, 1995). Water inflow and atmospheric forcing appear to serve as links in the signal transfer chain for the Bering Sea region. Their functioning reflects the direct effect of the atmosphere on the marine environment through the temperature regime of shelf waters, and the undirected oceanographic phenomena offshore. The signal propagates through changes in the general current pattern and tidal wave parameters, which determine the intensity of the water exchange between the shelf and open sea regions.

The direct effects of atmospheric forcing resulting from climate variations are very important to the physical oceanographic dynamics of the eastern Bering Sea shelf, which has a characteristically sluggish mean flow and is separated from any direct oceanographic connection to the North Pacific Ocean by the Alaska Peninsula. Therefore, linkages between the eastern Bering Sea shelf and the climate system are mainly a result of the ocean–atmosphere interaction (Stabeno et al., 2001). Climate variations in this region are directly linked to the location and intensity of the Aleutian Low pressure center which affects winds, surface heat fluxes, and the formation of sea ice (Hollowed and Wooster 1995). The pressure index shows eight statistically significant
Fig. 13.36. Regime shifts in the Bering Sea, 1968–2000 (composite of 31 physical indicators: Hare and Mantua, 2000).

shifts, alternating between cool and warm periods, over the 20th century, which occurred on roughly decadal time scales (Overland et al., 1999). A well-documented shift (Trenberth 1990; Hare and Mantua, 2000) from a cool to a warm period occurred between 1977 and 1989, which coincided with the commencement of fishery-independent sampling programs and fishery catch monitoring of major groundfish species. Information from the contrast between this period and the prior and subsequent cool periods (1960–1976 and 1989–2000) forms the basis of the following discussion of the response of eastern Bering Sea species to climate-induced system changes (Fig. 13.36).

13.5.3.1. Effects on primary productivity

The influx of Pacific waters northward into the western Bering Sea results in a warming effect. The dynamics of the environmental conditions of the Bering Sea offshore zone and the relatively narrow western shelf are largely determined by the periodic behavior of current patterns (Shuntov and Radchenko, 1999). The direction and velocity of these currents coincide with changes in the atmospheric circulation pattern, effects which are manifested through the change in intensity of the inflow of North Pacific Ocean water. From 1977 to 1989, a period of enhanced atmospheric transport, an intensification of currents into the Bering Sea resulted in enhanced fluctuations in the thermal properties of the system towards a warmer state. During those years, the effect of horizontal water movement and mixing on primary production was almost as important as vertical mixing due to the renewed supply of nutrients necessary for phytoplankton blooms. According to long-term data series, the highest concentrations of spring-time nutrients in the upper mixed layer were observed in the Aleutian straits, over the continental slope, and in areas where the influx of North Pacific water was present. The enhanced rate of primary production may be as much as 10 to 13 g C/m^2 per day (Sapozhnikov et al., 1993), which is more than can be used by the zooplankton and microheterotrophs (especially in the western Bering Sea shelf). The unutilized primary production accumulates at the upper boundary of subsurface waters, which is relatively cold for microheterotrophs, and the organic matter gradually rises into the upper layers in divergence zones and cyclonic eddies during the warm season. Therefore, favorable conditions for plankton development during spring, both from heating and nutrient supply from Pacific waters, may cascade through higher trophic levels and play a large role in determining the total biological productivity for the year (Radchenko et al., 2001).

Changes in atmospheric climate are mainly transmitted through the eastern Bering Sea physical environment to the biota through wind stress (Francis et al., 1998) and annual variation in sea-ice extent (Niebauer et al., 1999; Stabeno et al., 2001). These mechanisms directly alter the timing and abundance of primary and secondary production through changes in salinity, mixed-layer depth,

upwelling, nutrient supply, and vertical mixing. These environmental changes vary at a decadal scale and resulted in higher levels of primary and secondary production during the warm period of 1977 to 1988 than in the earlier cool period (Brodeur and Ware, 1992; Hollowed et al., 2001; Luchin et al., 2002; Minobe, 1999; Polovina et al., 1995; Sugimoto and Tadokoro, 1997). During periods of low summer storm activity in the Bering Sea region, as in 1993 to 1998, water column stratification increases. Heating of a thin surface layer above the seasonal thermocline prevents vertical nutrient transport from the underlying, stratified layers, which reduces levels of primary production and biological productivity in the Bering Sea (Shuntov et al., 1997), despite warmer surface water temperature. This is consistent with the total heat budget of the upper layer of the Bering Sea, which was lower in 2002 than in the warmer period of the previous decade (Fig. 13.37).

In the relatively warm years of 1997 to 1998, there was significant growth in euphausiid biomass in the western Bering Sea (Radchenko et al., 2001) suggesting that warmer waters provide favorable conditions for the survival and growth of some subarctic zooplankton species. Crustacean growth rates have also been found to be above average in warm conditions (Vinogradov and Shushkina, 1987; Zaika, 1983). This enhanced growth rate allows for a longer maturation period and spawning season. A meta-analysis of marine copepod species indicates that growth rate is positively correlated with increasing temperature and that generation time decreases, allowing more productivity in warmer climates (Huntley and Lopez, 1992). The oceanographic conditions in the epipelagic layer are not considered crucial for copepod reproduction in the Bering Sea, since copepod species reproduce in relatively stable deeper layers below 500 m. However, calanoid copepod biomass was much higher in the eastern Bering Sea
Fig. 13.37. Comparison of vertical temperature (°C) sections across the Kamchatka Strait on August 13–14, 1991 (black lines, after Stabeno et al., 2001) and June 27, 2002 (blue lines, TINRO-Center data, Vladivostok). Pink area indicates the layers where the water temperature was higher in 2002, green area – in 1991.

middle shelf in warm years (Smith and Vidal, 1986), probably due to higher growth rates. These findings suggest that climate change to a warm period enhances ecosystem productivity from the lower trophic levels, particularly for planktonic crustaceans.

13.5.3.2. Effects on sea-ice formation, distribution, and longevity

If it is assumed that any future climate change maintains the scale and periodicity of recent climate change events in the Bering Sea, then the period of meridional-type predominance in the wind transport above the Bering Sea, which began in the early 1990s, may last for 10 to 12 years before changing to a period of enhanced zonal transport. During the warm 1980s the zonal pattern of atmospheric circulation predominated (Luchin et al., 1998), as was the case in the 1920s and 1930s (Shuntov and Vasilkov, 1982). Periods of decreased zonal atmospheric circulation index (Girs, 1974) are characterized by colder arctic air masses over the Bering Sea region and a decrease in air temperature. The transitional 1989 to 1990 years were also characterized by a decrease in the zonal atmospheric circulation pattern above the far-eastern seas (Glebova, 2001; Overland, 2004).

Sea-ice distribution and residence time are frequently regarded as integral with the thermal regime of the Bering Sea pelagic zone (Ikeda, 1991; Khen, 1997; Luchin et al., 2002; Niebauer et al., 1999; Overland, 1991; Wyllie-Echeverria and Ohtani, 1999). The dynamics of sea-ice conditions directly depend on the intensity of the shelf water cooling in winter, wind direction, and water exchange between the shelf and the open sea. Similarly, ice conditions determine the intensity and degree of winter convection, the formation of cold near-bottom shelf waters, and the temperature distribution of surface and intermediate layers. The extent and timing of the sea ice also determine the area where cold bottom water temperatures will persist throughout the following spring and summer. This area of cold water, known as the "cold pool", varies with the annual extent and duration of the ice pack, and can influence fish distributions. For example, adult pollock have shown a preference for warmer water and exhibit an avoidance of the cold pool (Wyllie-Echeverria, 1995) such that in colder years they utilize a smaller proportion of the shelf waters and in warm years have been observed as far north as the Bering Strait and the Chukchi Sea.

13.5.3.3. Oscillating control hypothesis

During warm periods, favorable environmental conditions after the seasonal sea-ice retreat can result in a significant increase in the Bering Sea biological productivity. In contrast, physical factors during cold periods adversely affect zooplankton growth and biomass, and thus the viability of the pelagic fish juveniles feeding on this production. The "oscillating control hypothesis" proposes that the southeastern Bering Sea pelagic ecosystem alternates between primarily bottom-up control in cold regimes and primarily top-down control in warm regimes (Hunt et al., 2002). Late ice retreat (late March or later) leads to an early, ice-associated bloom in cold water (as occurred in 1995, 1997, and 1999), whereas no sea ice, or early ice retreat before mid-March, leads to an open-water bloom in May or June in warm water (as occurred in 1996, 1998, and 2000). Zooplankton, particularly crustaceans, are sensitive to water temperature. In years when the spring bloom occurs in cold water, low temperatures limit the production of zooplankton, the survival of larval and juvenile fish, and their recruitment. Such a phenomenon may be important for large piscivorous fish, such as walleye pollock, Pacific cod, and arrowtooth flounder. When continued over decadal scales, this situation leads to bottom-up limitation and a decreased biomass of piscivorous fish. Alternatively, in periods when the bloom occurs in warm water, zooplankton populations should grow rapidly, providing plentiful prey for larval and juvenile fish. In the southeastern Bering Sea, important changes in the biota since the mid-1970s include a marked increase in the biomass of large piscivorous fish and a concurrent decline (due to predation) in the biomass of forage fish, including age-1 walleye pollock, particularly over the southern part of the shelf (Hunt et al., 2002).

13.5.3.4. Effects on forage fish

Spatial distributions of forage fishes including herring, capelin, eulachon (*Thaleichtys pacificus*), and juvenile cod and pollock indicate temperature-related differences (Brodeur et al., 1999; Wyllie-Echeverria and Ohtani, 1999). Annual capelin distributions exhibit an expanded range in years with a larger cold pool and contract in years of reduced sea-ice cover. Although the productivity of capelin stocks in relation to temperature is not known, population growth of this relatively cold-water dwelling fish is not expected under the conditions of a warm regime. As discussed, capelin biomass increased when the abundance of walleye pollock and Pacific herring were low in the western Bering Sea (Naumenko et al., 1990), possibly due to a reduction in predation pressure of these species on capelin larvae. The eastern Bering Sea herring stocks showed improved recruitment in warm years (Williams and Quinn, 2000), similar to herring stocks on the Pacific coast of the United States where the timing of spawning is also temperature related (Zebdi and Collie, 1995). In the western Bering Sea, Pacific herring have also demonstrated a dependence on reproductive success related to the thermal conditions of coastal waters. However, herring stock increase and large-scale fishery restoration are related to the "historically most abundant" (Naumenko, 2001) year class, which appeared in the anomalously cold year of 1993. Generally, strong herring year classes have appeared in the western Bering Sea in years with high sea surface temperatures in May but the lowest sea surface temperatures in June

(Naumenko, 2001). After 2000, herring biomass decreased in the western Bering Sea but still exceeds the average level for the last warm period (1977–1989). In general, the distributions of all forage species from trawl surveys in a cold year (1986) were more widespread and with greater overlap among species than in a warm year (1987) (Brodeur et al., 1999).

13.5.3.5. Effects on pollock stocks

Pollock larvae concentrate in the water mass under the seasonal thermocline (Nishiyama et al., 1986). More productive year classes of pollock coincided with better nursery conditions for their larvae, which were related to a well-developed thermocline (pycnocline), large biomass of copepod nauplii, and low abundance of predators (Bailey et al., 1986; Nishiyama et al., 1986; Shuntov et al., 1993). The first two factors are related to warm conditions in the Bering Sea epipelagic layer. Age-1 pollock may also be distributed throughout the cold pool and move between water masses. During cold conditions, predation pressure on age-1 pollock is intense by their major piscine predators (adult pollock, arrowtooth flounder, and Pacific cod). As the cold pool reduced, predation on age-1 pollock increased due to overlapping distributions of Greenland halibut, yellow Irish lords (*Hemilepidotus jordani*), and thorny sculpins (*Icelus spiniger*) (Wyllie-Echeverria and Ohtani, 1999). The total biomass of the first group of predators was much higher in the 1980s than the second group (Aydin et al., 2002) and has remained higher until the present, despite some declines in western Bering Sea walleye pollock and cod stocks. In addition, the second group of predators comprises relatively small-sized fish (except Greenland halibut) and age-1 pollock could avoid predation through higher growth rates during warm conditions. In the relatively warm 1980s, strong year classes of pollock occurred synchronously throughout the Bering Sea (Bulatov, 1995) and coincided with above-normal air and bottom temperatures and reduced sea-ice cover (Decker et al., 1995; Quinn and Niebauer, 1995). These favorable years of production were due to high juvenile survival and are related to how much cold water habitat is present (Ohtani and Azumaya, 1995), the distribution of juveniles relative to the adult population to avoid predation (Wespestad et al., 2000), and enhanced rates of embryonic development in warmer water (Haynes and Ingell, 1983). Strong year classes of pollock were also observed in the eastern Bering Sea in the 1990s (Stepanenko, 2001), which may be related to the higher frequency of ENSO events, which contributed to heat transport throughout the region (Hollowed et al., 2001). However, there were no strong year classes of pollock in the western Bering Sea in the 1990s. This could be due to a general cooling of the Bering Sea climate and the oceanographic regime in a period of less intensive Pacific water inflow in the 1990s. The pelagic layer heat budget may need to be similar to that of the late 1970s and 1980s for the pollock reproduction conditions to improve in the Bering Sea as a whole.

13.5.3.6. Effects on other groundfish

Time series of recruitment and stock biomass have been examined for evidence that climate shifts induce responses in the production of groundfish species in the Bering Sea and North Pacific Ocean (Hollowed and Wooster, 1995; Hollowed et al., 2001). Even though results from these studies can be highly variable, strong autocorrelation in recruitment, associated with the significant change in climate in 1977, was observed for salmonids and some winter-spawning flatfish species. Substantial increases in the abundance of Pacific cod, skates, flatfish, and non-crab benthic invertebrates also occurred on the Bering Sea shelf in the 1980s as evidenced from trawl survey CPUE (Conners et al., 2002). This warm period was characterized by larger research catches and a change in the benthic invertebrate species composition from a system largely dominated by crabs to a more diverse mix of starfish, ascidians, and sponges.

In the southwestern Bering Sea, transition from the relatively warm period of 1977 to 1989 to the subsequent cool period was also evident in the groundfish community. The proportion of Pacific cod decreased from 80% in 1985 to 12 to 26.3% in the 1990s, while sculpin (8.2% in 1985) and flatfish (9.3% in 1985) proportions increased by 15.1 to 31.5% and 24.2 to 39.6%, respectively (Gavrilov and Glebov, 2002). Anthropogenic factors can also affect the state and dynamics of benthic communities. For example, large fishery removals of red king crab occurred in the 1970s and may have contributed to the reorganization of the benthos in the eastern Bering Sea. The climatic change related to recruitment success for winter-spawning flatfish may be associated with cross-shelf advection of larvae to favorable nursery areas, instead of with water temperature (Wilderbuer et al., 2002).

Sea-ice conditions and water temperatures can influence fishery effectiveness in addition to fish stock distributions and abundance. Coldwater effects have been observed in the behavior of flatfish species that may cause changes in the annual operation of the fishery. Because cold water causes slower metabolism in high latitude fish stocks, spawning migrations of yellowfin sole may be delayed in cooler years (Wilderbuer and Nichol, 2001), which can alter the temporal and spatial characteristics of the fishery. In addition, high catch rates have been obtained by targeting yellowfin sole close to the retreating ice edge, which has a high temporal variability and in warm years only occurs in areas north of the spring distribution of yellowfin sole. The catch process can also be affected as it is believed that flatfish bury themselves in muddy substrate during cold years and so become less vulnerable to herding by the sweep lines of bottom trawls (Somerton and Munro, 2001). This would result in lower catch rates in cold years for shelf flatfish species. These temperature-related behavior effects may also occur in other commercial species, particularly in pelagic fish, which react to avoid capture (Sogard and Olla, 1998).

13.5.3.7. Effects on salmon

Throughout their century-long exploitation, Alaskan salmon stocks have had periods of high and low production which persist for many consecutive years before abruptly reversing to the opposite production state. These production regimes coincide with low frequency climate changes in the North Pacific Ocean and the sub-arctic Bering Sea (i.e., the Pacific Decadal Oscillation and the Aleutian Low Pressure Index). In the 1930s and early 1940s, and then again in the late 1970s, Bering Sea salmon catches reached high levels during warm temperature regimes in their oceanic habitat. It is hypothesized that improved feeding conditions may prevail during warm oceanic regimes (Hare and Francis, 1995). There is also evidence of an upper thermal tolerance for salmon species that has set limits on their distributions (Welch et al., 1995), but it is doubtful that this effect would occur in the Bering Sea because the historical temperature range there is much lower.

13.5.3.8. Effects on crab stocks

The three species of crab that inhabit the eastern Bering Sea shelf (red king crab, Tanner crab, and snow crab) exhibit highly periodic patterns of increased abundance. Rosenkranz et al. (2001) investigated five hypotheses on factors affecting year class strength of Tanner crab in Bristol Bay in order to understand these patterns. They determined that anomalously cold bottom temperatures may adversely affect the Tanner crab reproductive cycle and that northeast winds may promote coastal upwelling, which advects larvae to regions of fine sediments favorable for survival upon settling. Incze et al. (1987) linked low densities of copepods inside the 70 m isobath of Bristol Bay with low abundance of Tanner crab larvae. An examination of recruitment patterns of red king crab in relation to decadal shifts in climate indicates that the Bristol Bay stocks are negatively correlated with the deepening of the Aleutian Low and warmer water temperatures (Zheng and Kruse, 2000). Red king crabs were also moderately exploited during the late 1970s, which contributed to the population decline.

13.5.4. Possible impacts of climate change on fish stocks

Given the present state of knowledge of complex marine ecosystems such as in the Bering Sea, it is not possible to predict with any certainty the effects of future atmospheric forcing, in this case increased sea surface temperature, on commercial fish and invertebrate species. Evaluation of a future state of nature would require knowledge of the future values of many ocean–atmosphere parameters to describe how these changes would be manifested in upper trophic level commercial stocks. These parameters include storm activity and frequency, wind direction and intensity, shelf stratification characteristics, effects on circulation and transport activity, sea level pressure (location and intensity of the

Aleutian Low pressure system), and precipitation as well as projections of sea surface temperature.

Three future climate scenarios are considered for the Bering Sea: no change from present conditions; moderate warming; and considerable warming.

13.5.4.1. No change

Under the no-change scenario the Bering Sea climate will continue to exhibit decadal-scale shifts alternating between warm and cool periods. These shifts in temperature regime have been shown to favor some species while their effect on others is unclear (section 13.5.3.4 to 13.5.3.8).

Under the present US and Russian management systems, it is expected that fish and invertebrate populations would be at or rebuilt to target spawning biomass levels as dictated by the management plans. This should result in an increase in total catches from the Bering Sea. Over the long term, however, a large total average increase is unlikely, but could nevertheless be considerable in individual cases.

13.5.4.2. Moderate warming

A moderate warming scenario can be developed by extrapolating trends characterizing the decadal-scale variability in the key physical factors influencing the Bering Sea ecosystem. On the basis of a moderate increase in air temperature (of 1 to 3 °C) and a general warming of the upper pelagic zone, several changes are likely:

- an increase in the zonal type repetition of atmospheric circulation for the early 2000s and for the period of the next 11-year cycle of solar radiation;
- an increase in storm activity and wind-induced turbulence for the same period;
- a gradual increase in water exchange with the Pacific Ocean, reaching a maximum in 2015 to 2020; and
- reduced sea ice, accelerated by an increase in air temperature, for the next 10 to 20 years after which time sea ice might increase again.

Variability in solar radiation correlates with many phenomena (Schumacher, 2000). It is a potential forcing mechanism for decadal-period oscillations of the coupled air–ice–sea system in the northern-hemisphere (Ikeda, 1990). Changes in solar fluxes correlate with change in the height of an atmospheric pressure surface in the troposphere of the northern-hemisphere (correlation coefficient = 0.72; Van Loon and Shea, 1999). Spectral maxima occur roughly every 7–17 (with an average of 11) and 22 years. The North Pacific Index also has phases similar to those noted for changes in solar radiation (Minobe, 1999). Storm activity and wind-induced turbulence of the sea surface layer are determined by the tracks and strength of cyclones, which are in turn deter-

mined by the nature of the pressure field. In the Bering Sea, a strong Aleutian Low is the source of most of the storm energy, and results in intense mixing of the sea surface layer in winter. Strengthening of the Aleutian Low occurs in years of zonal air transfer predominance (Shuntov, 2001). Such interrelations enable a prediction of high storm activity and wind-induced turbulence for all of the next 11-year cycle of solar activity.

Available information for the recent warm period in the Bering Sea suggests that primary productivity, and thus carrying capacity, would be enhanced under the warming scenario. However, because mixed-layer depth and water movements are not available for this scenario, the extent of this increase cannot be predicted owing to uncertainties concerning the renewal of the nutrient supply essential for sustaining the phytoplankton and zooplankton blooms. Also, as spring blooms are associated with the ice edge, a decrease in sea-ice extent associated with climate warming could

delay the onset of primary production in spring (Hunt et al., 2002). High water-column stability, which occurs at the ice edge during ice retreat, also supports intense phytoplankton blooms.

Recent studies on phytoplankton sinking velocities show that diatom cells sink more quickly than flagellates, which are lighter (Huisman and Sommeijer, 2002). Thus, it is possible that iceless winters could create unfavorable conditions for diatom blooms. This implies that climate warming could result in decreased biological production in the Bering Sea until the start of the projected increase in sea-ice cover after 2010. The dynamics of the Bering Sea sea-ice conditions are characterized by several periods of cyclic recurrence, ranging from 2–3 to 50 years (Plotnikov, 1996; Plotnikov and Yurasov, 1994; Ustinova and Sorokin, 1999). Obviously, this series is short for an exact tracking of the 50-year cycle. However, dramatic shifts in ice-cover anomalies were noted in the Bering and Chukchi Seas between 1976 and 1979, which divide

Table 13.2. Changes to stocks in the western Bering Sea and projected stock dynamics in response to a moderate warming (+ positive effect evident, - negative effect evident, 0 no effect evident or unclear effect).

the 1952–1994 data series into two distinct periods, which differ by 5.4% in average values (Niebauer et al., 1999). Alternatively, a warmer period could increase thermal stratification such that the bloom, which is not ice-dependent, would start sooner. However, it could also be that the nutrient supply is quickly depleted during a short and intense bloom and that photosynthesis is slowed. In addition to upwelling and nutrient recycling in the pelagic layer, Pacific water inflow is also a source of nitrogen and phosphorus. Intensification of water exchange with the Pacific Ocean under climate warming is thus likely to result in increased primary production in the Bering Sea (Shuntov et al., 2002, 2003; Ustinova, and Sorokin, 1999). Increased levels of primary production are usually associated with improved survival for juveniles of most fish species (Cushing, 1969) and subsequent contribution to the adult spawning stock.

Predictions of the relationship between climate change and commercial species distribution, abundance, and harvest patterns are based on the assumption that future management policies will be the same as at present. Namely, that target fishing mortality values will be designed to maintain the female spawning stock at a minimum of 40 to 60% of the unfished level (depending on species). Also, that when stocks are assessed to be below this level, harvest is reduced proportionally to rebuild the spawning stock to the target level. This approach is likely to result in fisheries for species which respond favorably to warmer conditions realizing greater catches and possibly shifting to areas of increased abundance or expanded habitat, while fisheries for species which are negatively affected by a warmer climate are likely to have smaller quotas, reduced areas of operation, and even vastly different areas.

Literature documenting changes in the Bering Sea ecosystem under the previous warm period suggests that increases in the abundance of many groundfish species are very likely under future warming. Pollock, Pacific cod, Pacific halibut (Clark and Hare, 2002), skates, some flatfish species, salmon, eastern Bering Sea herring, and Tanner crab are all likely to benefit under warmer conditions (Table 13.2), although the mechanisms underlying the increase are not clear in most cases. Strickland and Sibley (1984) proposed a possible northward expansion of pollock feeding and spawning habitat under a warming scenario due to reduced sea-ice cover, water column stratification, and increased food supply.

There are very likely to be many changes in the Bering Sea ecosystem following a change to warmer conditions from those at present. Centers of capelin distribution are likely to move northward to colder waters and forego the large areas of spawning habitat that would be available in colder years. Polar cod and five species of marine mammals that are associated with the ice edge (harbour seal, Steller sea lion, sea otter, beluga whale, and Dall's porpoise) are likely to be restricted to the Chukchi Sea for large parts of the year. Red king crab, which decreased in abundance during the past warming

period, is unlikely to do well under future warming. Deep-water species such as Greenland halibut are unlikely to be affected during their larval and juvenile stages, except when they are present in shallow water. Greenland halibut recruitment is likely to be enhanced in colder years, perhaps due to a decrease in overlap with adult pollock (Livingston et al., 1999). Similarly, predation by large piscivorous fish is likely to affect the pandalid shrimp stocks; these shrimp species are among the preferred prey of Pacific cod during summer feeding in the northern Bering Sea, especially for new recruits (Napazakov et al., 2001). Predation on shrimp stocks is likely to increase with increased recruitment of Pacific cod. Annual consumption of gonatid squid species was estimated at 4.2 million t in the Bering Sea for the late 1980s (Radchenko, 1992). A growth in squid stocks is unlikely under a warming regime due to predicted increases in the abundance of their main predators (except for Greenland halibut). Increased abundance of sculpins and western Bering Sea herring in the 1990s was attributed to the weakening of interspecific competition in the pelagic and benthic fish communities by Naumenko et al. (2001). These stocks are likely to experience future decreases due to increases in pollock stock size.

Although some flatfish species on the Bering Sea shelf have shown increased productivity under warmer conditions, their distributions are unlikely to shift in response to ocean temperature. These species migrate to deeper, warmer waters in winter (where some spawn) and then migrate to the mid-shelf area in spring and early summer where they feed on the benthic infauna. Site fidelity is important for feeding purposes and these species are likely to tolerate moderate thermal changes. Habitat specialists, which have successfully developed niche preferences, are much less likely to be affected by climate change than "colonizing" species which have a more diverse diet so might be inclined to shift with the changing conditions. Such characteristics are expected to influence the extent to which fisheries would change under a warmer climate. However, the total fishery catch occurring under a climate change scenario would only increase to the extent allowable under current management practices. This also corresponds to historical data for the western Bering Sea fishery (Fig. 13.35). Attempts to forecast this increase, as described in the rest of this section, are based on the previously achieved maximum fishery harvest and assume that current management philosophies continue.

The maximum pollock catch in the Bering Sea was 4.07 million t in 1988, and averaged 3.55 million t between 1986 and 1990 (Fadeev and Wespestad, 2001). The total walleye pollock biomass in the Bering Sea over that period was about 20 million t (Shuntov et al., 1997). Conventional wisdom assumes that the 1990s stock reduction was due to a decrease in productivity in response to environmental conditions rather than to overfishing. This means that the pollock harvest in the favorable period of the late 1980s can be used as the ref-

erence point for predicting future catch for the projected warm period. As a rule, an increase in the pollock fishery stock is due to several average and strong year classes, as in the latter 1960s, or one super-strong year class. A super-strong generation appeared in the Bering Sea in 1978 and ensured a stabilization of stock abundance and the development of the large-scale pollock fishery at the end of the 1980s (Stepanenko, 2001). The eastern Bering Sea population of pollock almost doubled between 1995 and 2001 and supports an annual catch of more than 1 million t with strict regulations. The stable condition of this population provides for the likely increase in future abundance associated with a moderate climatic warming. However, the 1978 year class occurred 13 years after the first strong year class in 1965 (Wespestad, 1993) and no cohorts of this strength have been observed since. Thus, a swift increase in stock size and catch of pollock in the near future is unlikely.

The annual Pacific cod harvest ranged from 33 100 to 117 650 t and averaged 65 210 t in the western Bering Sea during the period of Dutch seine trawls and, to a lesser degree, longline fisheries between 1981 and 2001. The catch for the whole Bering Sea for that period totaled 207 110 t. This is a relatively low catch compared to an estimated cod biomass of 3.27 million t. Adult Pacific cod are the main predator for some commercially important fish (e.g., pollock and herring) and crustaceans, particularly Tanner crab and shrimp. Relative to their weight, one unit of Pacific cod biomass consumes about 1.11 biomass units of Tanner crab juveniles, 1.12 of shrimp, 0.8 of walleye pollock, 0.39 of squid, and 0.31 of herring on the western Kamchatka shelf during the six months of the warm season (Chuchukalo et al., 1999). Whether an assumed increase in fishing pressure is justifiable for the purpose of decreasing predation by Pacific cod on other species in the ecosystem is under investigation. If the Pacific cod stock attains the same abundance in the Bering Sea as in the mid-1980s, it is likely that the total harvest could be increased (in both the western and eastern Bering Sea) to the level experienced in the 1980s and 1990s, i.e., around 350 000 t.

Fig. 13.38. Long-term changes in pelagic fish biomass in the western Bering Sea, 1951–2000 (after Naumenko et al., 2001).

Between 1981 and 1991, herring fisheries in the southeastern Bering Sea, in the vicinity of the Alaskan coast, harvested around 30 000 t, while harvests in the southwestern part of the Bering Sea (Fig. 13.38) were around 17 000 t over this period, relative to a total biomass level of nearly 500 000 t. The same level of harvest is likely for the next warm period. The western Bering Sea "fat herring" fishery is very likely to decline during the next decade, but the Alaskan roe-sac herring fishery is likely to increase.

The Pacific salmon fishery recently surpassed its top harvest level in the northeastern Kamchatka area due to the record pink salmon catches in 1997 (82 300 t) and 1999 (83 600 t). However, some decline is likely to occur there since the local stocks of other Pacific salmon species are not as abundant. The chum salmon coastal catch did not exceed 12 200 t, while the sockeye salmon catch did not exceed 7000 t for these years. However, these relatively high catches were made in the latter half of the 1990s. On the basis of the 5-years rate of increase in the 1990s, the total chum and sockeye salmon harvest could reach a surplus of 20 and 12%, respectively, by the end of the 2020s. Eastern Bering Sea salmon production is dominated by sockeye salmon which contributed 41 million fish from a total catch of 42 million Pacific salmon in Bristol Bay in 1993. This was a historical record and followed the previous record of 37 million fish (101 550 t) in 1983 (National Research Council, 1996). The Bristol Bay sockeye stock has since declined and is presently in a period of low production. Stock dynamics observed over the 1960s to 1990s (Chigirinsky, 1994) suggest that periods of low productivity can last for 15 to 20 years and with an average annual sockeye catch of about 20 000 t. However, if moderate climatic warming is favorable for Pacific salmon growth and survival during the marine part of its life cycle, it is likely that the annual catch will approach that of the previous warm period (1977 to 1993), i.e., about 110 000 t. The proportion of sockeye salmon is very likely to increase from the mid-2000s to the 2020s from 25 to 30%, to 50 to 55% of the total and the proportion of pink salmon will decrease accordingly. Chum salmon are very likely to take third place, chinook salmon fourth, and coho salmon fifth.

Although flatfish biomass will possibly increase in future warm periods, the catch is likely to remain low due to bycatch and market constraints. The Atka mackerel (*Pleurogrammus monopterygius*) of the Aleutian Islands, skates, smelt, and saffron cod (*Eleginus gracilis*) of the southeastern shelf are other potential stocks in good condition. Development of new markets for these fishery products could increase future harvests. Comments concerning a future crab fishery in the Bering Sea cannot be made as it is not well understood which environmental conditions would enable better survival and growth of crab larvae and juvenile stages. Also, the reasons for the sharp crab stock decrease in the Bering Sea in the 1980s are not known and there is debate as to whether the decline was due to overfishing or environmental

change. Polar cod, capelin, sculpin, mesopelagic fish, shrimp, and squid fisheries are presently undeveloped in the Bering Sea, and no precondition exists to develop these fisheries under a warmer climate regime. Some bycatch of commander squid (*Berryteuthis magister magister*) and sculpins in the trawl fishery for pollock in the Dutch seine fishery on groundfish is used, but the total value of this harvest is insignificant.

13.5.4.3. Considerable warming

Since a warming of >4 °C has not previously been observed, it is not possible to comment on changes which might occur in the marine ecosystem based on past cause and effects. It is likely that the distributions of many species would shift poleward and that there would be significant changes in the arctic ecosystem. Ice-associated species would encounter a shrinking habitat and there would be greater potential for stock collapse for species forced to forego past areas of desirable spawning and nursery habitats due to thermal intolerance. The species succession likely under a scenario of considerable warming is not known, but a sudden reduction in the economic potential of Bering Sea fisheries is possible.

13.5.5. The economic and social importance of fisheries

In comparison to other areas of the Arctic, the commercial fisheries of the North Pacific, including the Sea of Okhostk, and the Bering Sea, are relative newcomers. Near-shore artesanal fisheries by indigenous peoples have occurred for centuries in the Bering Sea (Frost, 2003; Ray and McCormick-Ray, 2004; see also Chapters 3 and 12). The first documented commercial exploitation of groundfish dates back to 1864, when a single schooner fished for Pacific cod in the Bering Sea (Cobb, 1927), although salmon were part of commerce during earlier times. In 1882, American sailing schooners began a regular handline cod fishery. As recorded in Russian literature, the California-based fishers ceased to sail to fish in the Sea of Okhotsk after the cod shoals near the Shumagin Islands in the Gulf of Alaska were discovered. In the western Bering Sea, the early Russian fisheries were poorly developed and limited to near shore subsistence fishing by indigenous peoples and settlers (Ray and McCormick-Ray, 2004). However, even at this early date the Bering Sea was known to contain a rich resource of fish. The herring fishery area expanded northward to the Bering Strait and operated during two weeks in May when herring migrated near the coasts. The Pacific salmon fishery yielded 12 million fish each year of which 2 to 4 million fish were from the Yukon Delta area, while the remainder were caught by Russian development companies and Japanese corporations operating concessions on Russian rivers (Netboy, 1974).

In contrast to the slow development of the early fisheries, the hunting of marine mammals developed rapidly. In the western Bering Sea, the fur seal harvest ranged from 20 000 to 50 000 animals on the Commander Islands. A Russian–American Company was mainly responsible for the hunting and fur purchase operations in the eastern Bering Sea, Gulf of Alaska, and Aleutian Archipelago regions between 1786 and 1862. The sea otter harvest totaled 201 403 animals during the time of the Russian–American Company of which nearly a third was purchased by merchants from the indigenous peoples. Other marine mammal harvests included sea lion hunting on St. George Island (on the Pribilof Archipelago), which yielded 2000 animals per year, and walrus hunting, which yielded 300 to 2000 animals per year until the harvest was reduced in the 1830s due to a declining population. Owing to overexploitation, the fur seal breeding grounds disappeared from the Pribilof Islands, Unalashka Island, and adjacent areas in 1830 to 1840. From 1743 to 1823, 2 324 364 fur seals, 200 839 sea otters, about 44.2 t of walrus tusk, and 47.8 t of baleen were harvested from the Aleutian Arc, other islands, and the Alaskan coast. The first protective measures on fur seal populations from Japanese and American illegal sealers were set by Russia in 1893. There is an illustration of this in the Rudyard Kipling ballad *The Rhyme of the Three Sealers*:

> *Now this is the Law of the Muscovite, that he proves with shot and steel*
>
> *When ye come by his isles in the Smoky Sea ye must not take the seal.*

In 1911, a three-sided treaty was concluded between Russia, the United States, and Japan, which established a sealing prohibition on the high seas in exchange for compensation paid from harvests in the rookeries (Miles et al., 1982a,b).

Large-scale commercial exploitation of the Bering Sea fish stocks developed slowly. Between 1915 and 1920, as many as 24 US vessels fished Pacific cod. Annual harvests ranged from 12 000 to 14 000 t (Pereyra et al., 1976). Small and infrequent halibut landings were made by US and Canadian fishers between 1928 and 1950, which increased sharply and exceeded 3300 t between 1958 and 1962 (Dunlop et al., 1964). In the early 1970s, the halibut catch fell to a low of 130 t before recovering to a high in 1987, and then slowly declined. The International Pacific Halibut Commission, established by Canada and the United States in 1923 to manage the halibut resource, determined that factors such as over-exploitation by the setline fishery, juvenile halibut bycatch, and adverse environmental conditions led to the decline in abundance (National Research Council, 1996). In the western Bering Sea, the exploitation of groundfish resources was mainly by small-scale coastal operations. Information on groundfish abundance was lacking until the first Soviet Pacific Integrated Expedi-tion in 1932 to 1933. This covered the entire Bering Sea and found the eastern shelf and continental slope to be more productive fishing grounds than the narrower western ones. As a result, Soviet fish-

eries concentrated their efforts in the eastern Bering Sea after 1959. By the mid-1960s, newly organized Soviet fishing on the eastern Bering Sea shelf and in the Gulf of Alaska yielded about 600 000 t of Pacific ocean perch, yellowfin sole, herring, cod, crabs, and shrimps (Zilanov et al., 1989).

The Japanese and Russian fleets expanded rapidly between 1959 and 1965, with vessels from the Republic of Korea and other nations also participating in later years. These fishery efforts were added to the solely Japanese fishery efforts, which have actively operated in the Bering Sea since the 1930s, especially after the Second World War. By 1960, 169 vessels from Japan were present on the Bering Sea fishing grounds along with 50 to 200 vessels from the Soviet Union (Alverson et al., 1964). Significant growth in fishing effort led to overfishing of several stocks. The Soviet walleye pollock fishery began in the early 1970s after the decline of some commercially valuable fish stocks. Before that, walleye pollock was not regarded in the Soviet fishery as a target species. The Japanese mothership operations had three to five conventional catcher/trawlers and as many as eight pairs of trawlers associated with each mothership (Alverson et al., 1964). The catch was processed at sea with the frozen products transported ashore for food. Japanese catches were mostly processed aboard mother-ships into fishmeal, with livers extracted for vitamin oil. Female walleye pollock in spawning condition soon became an important source of roe-bearing fish, which were processed into valuable products such as different kinds of fish roe and surimi. The increase in product value, combined with an increase in pollock abundance after the latter half of the 1960s led to the gradual increase in catch: up to 550 000 t in 1967 and 1 307 000 t in 1970 (Fadeev and Wespestad, 2001). Groundfish catches were mainly by vessels from Japan and the Soviet Union until 1986, when US fishing vessels participating

in joint ventures with foreign processing vessels took a larger proportion of the catch. By 1990, the distant water fleets were phased out of the eastern Bering Sea (the US EEZ) and US fishing vessels became the sole participants in the fishery. Some fishing occurs under license from the Russian Federation in its EEZ.

13.5.5.1. Fisheries

United States fisheries off Alaska constitute more than half of landings and about half the value of national landings of fish and shellfish from federal waters (NMFS, 2003a). Depending on species, approximately 90% of the landings in Alaska are from the Bering Sea/Aleutian Islands area. All the groundfish, crab, and salmon in the US EEZ of the Bering Sea are caught by domestic fishing bodies (Hiatt et al., 2002). In the Russian EEZ the majority of the harvests are taken by domestic fleets with a decreasing amount harvested under agreements with neighboring states. In 1997 it is estimated that the Russian Far East fisheries accounted for 70% of the Russian Federation total fisheries production (Conover, 1999; Zilanov, 1999), however this proportion may be decreasing due to the declines in pollock, crab, herring, and other species not being off-set by the increases in Pacific salmon.

In the Bering Sea, walleye pollock is the major harvest by volume and value, with Pacific cod, flatfish, salmon, and crabs constituting most of the rest (Table 13.3). The total wholesale (raw fish landings) value for ground-fish harvests in the eastern Bering Sea was approximately US$ 426 million in 2001. The total primary processed value was approximately US$ 1.4 billion. Crab harvests, mainly from the Bering Sea/Aleutian Islands area, amounted to US$ 124 million even at the low population abundances noted earlier (Hiatt et al., 2002). Pacific salmon, a large amount of which comes from the Bristol

Table 13.3. Trends in abundance and value of major Alaskan fisheries (inflation-adjusted US dollars) (Alaska Department of Fish and Game, as cited by Pacific Fishing, January 2002).

Species	Stock 1977	Value 1977	Stock 2001	Value 2001	Discussion
Salmon	200 million fish	US$ 500 million with peak value in 1988 of US$ 1.18 billion	175 million fish	US$ 205 million	A small decrease in total catch but a large decrease in price due to competition with farmed fish
Groundfish	Very small US harvest	US$ 2–3 million but rapidly increasing to US$ 1.0 billion in 1988 as a result of Americanization	1.65 million t harvested	US$ 400 million	Whitefish markets strong yet price weak but US dollar also weak
Shellfish (primarily crab species but some shrimp in early years)	Red king crab strong, other species small harvests	US$ 440 million. Drops when red king crab bubble bursts but Opilio crab takes over	Most species at low levels	US$ 125 million	Strong competition in Opilio fishery from Eastern Canada but weak competition from Russia
Pacific halibut	Low catch most likely due to foreign fleet bycatch	Less than US$ 30 million	High abundance	US$ 150 million	Strong stocks and good price vis a vis other white fish
Herring	Low abundance	Less than US$ 30 million although value increased in mid-1980s/mid-1990s to US$ >50 million	Low abundance	Less than US$ 30 million	Herring in same situation in 1977 and 2001

Bay and Yukon River areas, had a Bering Sea catch value of between US$ 122 million (2001) and US$ 179 million (2000) (Link et al., 2003). The Community Development Quota (CDQ) Program, which allocates 10% of the total Bering Sea TAC to 65 coastal communities organized into six CDQ corporations, earns more than US$ 40 million annually (NPFMC, 2003a). A separate value is not assigned in this study to recreation or subsistence harvests in the Bering Sea due to lack of adequate analyses, despite their local and cultural significance. Economic value data for the Russian Far East are difficult to locate (Pautzke, 1997). Press reports for product value estimate the total 2001 production to account for US$ 3.0 billion (Pacific Rim Fisheries Update, May 2002). Since the transition to a market economy began in the early 1990s and the Soviet style management of fisheries has changed, it appears that there are significant tracking and reporting difficulties with less fish being landed to avoid taxation and fees. Instead, harvests may be transferred at sea or transported directly to foreign markets by fishing vessels (Velegjanin, 1999). Thus, production and value data must be treated with caution until a more robust accounting system is developed.

13.5.5.2. Fishing fleet and fishers

Almost every fishing vessel in the Bering Sea fleet is registered outside the region. Vessels must be of requisite size to weather the environmental conditions and to have adequate scale efficiencies to operate in the area. These factors plus the lack of deepwater moorings and other support services make the eastern North Pacific a largely "distant water" fishery. Overall, the number of vessels eligible to fish for the increasing stocks of groundfish in the federal waters of the Bering Sea has decreased since the mid-1990s from 464 vessels in 1995 to 398 in 2001. This is the case for all groundfish vessel classes and types. In 2001, there were 163 hook and line (longline) vessels, 81 pot vessels, and 162 trawl vessels fishing, of which around 20 were at-sea capture/processors for pollock. The overall decrease in number results from rationalization programs for pollock under the American Fisheries Act 1998 and the North Pacific Fishery Management Council's license limitation program for all species (although this figure does not include halibut/sablefish vessels which have Individual Fishing Quota qualification) (Hiatt et al., 2002). For other sectors, there were around 274 eligible Bering Sea/Aleutian Islands crab fishing vessels, 2500 catcher longliners (including Alaska state-water vessels) mostly involved in halibut/sablefish and Pacific cod fisheries, and some 5200 salmon fishing vessels of various types (Natural Resources Consultants, 1999).

Employment in the groundfish harvesting sector (at-sea catching and processing on land as well as motherships) in 2001 amounted to 4000 full-time equivalent jobs including skippers, fishing crew, processing crew, and home office staff (NMFS, 2003b). With few exceptions, most of this employment is in relatively small corporations. North Pacific Fishery Management Council license

limitation regulations limit the size and ability to grow of existing catching bodies. Thus, few large integrated harvesting and processing companies exist. Still, even the smaller organizations deal in multi-million dollar investments with substantial annual operating expenses, e.g., a typical catcher vessel of about 35 to 40 m in length would require a family owner or small business to have a fair market value of US$ 2.5 million to 3.5 million (Natural Resources Consultants, 1999).

In the western Bering Sea, the situation is similar to that in the Alaskan EEZ. A large part of the harvesting capacity is located in the southern parts of the area, as are the financial and supply and repair services. The number of fishing vessels has declined drastically since the end of the Soviet era distant water fishing, owing to other nations extending their EEZs and to efforts to renew the fishing fleet and to reorganize it on market economy terms (Zilanov, 1999). Between 1990 and 1999 the Russian fishing fleet decreased by nearly 44% in number. Most of the fleet was privatized in the form of joint stock companies (56.7%), or transferred to cooperatives (*kolkhozes*; 23.7%), private companies (12.5%), or joint Russian–foreign ventures (2.4%) (Zilanov, 1999). In the Russian Far East, this has enabled small and mid-scale fisheries to develop while some large entities under Soviet style fisheries have changed and remained dominant forces. Likewise, total employment in the fisheries sector fell from 550 000 in 1990 to 398 000 in 1998. Contributing to the decline in employment in the Russian Far East was an exodus of people assigned to duties there returning to families and friends in their home regions.

13.5.5.3. The land side of the fishing industry

Approximately 70% of the Bering Sea harvests are processed on shore in a relatively small number (8) of groundfish processing plants near Dutch Harbor/Onalaska (NMFS, 2003b). Recent efforts have been made to locate processing facilities on Adak Island in the western Aleutians. Crabs are processed on the Pribilof Islands during periods of high abundance of red king crabs and snow crab in the Bering Sea. Salmon tendering and processing is focused around Bristol Bay although not exclusively. Sites where processing occurs require significant infrastructure for processing as well as for providing services to the fishing fleet. Given the remote nature of the Bering Sea fish processing activities, the communities in which these occur are highly dependent on the fishing industry for economic activity, with government services and tourism distant rivals. Most of the groundfish processing occurs adjacent to the densest aggregations of groundfish and where catcher vessels with refrigerated sea-water holds can make relatively rapid trips to maintain product quality. However, for some species and products (e.g., high grade surimi) it is difficult for shoreside processors to compete.

Employment in Alaskan shoreside processing for groundfish is estimated at 3525 full-time equivalents (NMFS,

2003b). The number of processing jobs onshore in the Bering Sea has increased by as much as 50% between the early 1990s and the present because of policies decreasing the amount allocated to at-sea processing versus onshore processing. Much of the work force is an ethnically diverse group of work permit holders from other parts of the world, mostly west coast United States, Mexico, and the Philippines. Over time, Alaskan communities in the Bering Sea region are being transformed as workers stay on and climb the corporate ladder.

In the Russian Far East a significant proportion of the catches have been processed at sea with the rest processed on shore or kept in cold storage, etc. With domestic demand low in terms of the ability to compete with global market price and other tax and regulatory issues onshore, there is a substantial incentive to process offshore and export directly (Velegjanin, 1999). This has contributed to a sizeable decrease in domestic consumption and employment in shoreside processing and other services to the fishing industry. The transition to a market economy has been difficult but the learning curve is trending upward with new management institutions and experience. However, without the full cooperation of the fishing industry and management, and tensions over the allocation of revenue between the Far East and Moscow, it will be some time before the industry stabilizes.

13.5.5.4. Fisheries communities

The North Pacific fishing communities surrounding the Bering Sea are different to those of the North Atlantic. There is no history of small coastal fishing communities developing commercial fishing on the currently harvested large stocks of pollock, Pacific cod, etc. In the eastern Bering Sea some 65 communities exist with a total population of around 27 500. They are frequently inhabited by a large percentage of indigenous Alaskans, but not exclusively (NPFMC, 2003a). Until they became participants in the CDQ program, they had limited coastal subsistence fisheries as well as some small-scale commercial fisheries for salmon and halibut. Involvement in the groundfish and crab fisheries has provided valuable income and employment as well as a role in management of the offshore fisheries. The main location of the fish processing on Akutan and Dutch Harbor/ Onalaska had been important for crab, halibut, and some salmon fisheries. It was not until foreign and domestic investment was encouraged in shoreside processing of groundfish in the late 1980s that these communities were transformed. Loss of access to fishing in the US EEZ prompted Japanese investment in processing so that raw fish could be purchased at low prices and benefits gained in value-added processing from shore-based plants.

The history of the purchase of Alaska from Russia in 1867 and its status as a territory until Statehood in 1959 was that of a domestic colony. In particular, fishing interests in western Washington and Oregon were some of the prime early investors in Alaskan fisheries. Ownership of the highly seasonal Alaskan canneries was mostly outside Alaska. Salmon fishing brought labor from the south. Halibut fisheries were developed as soon as ice-making and refrigeration technologies permitted catching and transport of fish to southern markets. Early crab fishing interests were based out of Seattle. Thus, the fisheries of Alaska have strong personal, financial, and service connections to Seattle due to the laws of comparative advantage. Alaska is a high cost area for living and carrying out a business (Natural Resources Consultants, 1999). In the federal water fisheries, residents of other states must not be discriminated against in management regulations, which further enforces the long, mostly cooperative, relationship between fishing interests in Washington and Oregon and those in Alaska. Overall dependence on fisheries varies by community but in Alaska as a whole, fisheries is a distant second to oil production in terms of revenue from resource extraction and for some cities with onshore processing, fisheries are the prime source of local landing tax revenue.

Similar to Alaska, small indigenous Russian settlements existed around the western Bering Sea. With the colonization by Russians, larger towns developed and during the Soviet era these grew as bases for resource development and national defense. Population in the seven administrative regions of the Far East is concentrated in coastal cities and declined slowly throughout the 1990s (Zilanov, 1999). Several large cities account for the majority of the population such that much of the Russian coastline is undeveloped. Fisheries are dominated by fishing interests in Vladivostok and Nakhodka. Increasingly stronger demands are being made by other regional fishing bases for more autonomy in management and greater allocations to proximate users.

13.5.5.5. Markets

The relatively low populations of the Bering Sea region do not constitute a very large local market for the large-scale fisheries. Thus, both Alaska and the Russian Far East look to distant markets at home and abroad. For Alaska, the prime markets are Japan, Korea, and China with Europe providing entry for some products. Over 90% of Alaskan fish is exported. Korea and now China with their relatively low wage labor have served as processing centers for some products that are re-exported, i.e., imported back in some value-added form. For the Russian Far East, exports have started to play an increasing role in the fisheries economy. During the Soviet era up to 80% of the Far Eastern fish products were processed and sent on to domestic markets in the western more populous parts of the country. The rest was exported or taken under fisheries agreements with neighboring states to obtain hard currencies needed by the central government. While low effective demand (i.e., domestic consumers) is not able to pay international prices for seafood products, many of the higher value species are exported and low value species and products are imported so that around 50% of the

seafood harvested is destined for export (Zilanov, 1999). Thus, the remote Bering Sea is a major player in terms of global seafood markets where declines in abundance of Atlantic cod, for example, open markets for fillets of pollock at the same time demand for pollock surimi products seems to be slackening as a result of weak Japanese and Korean markets. Similarly, high abundance of snow crab in Canada causes market erosion for this species in the eastern Bering Sea.

Owing to the significant price competition from farmed Atlantic salmon, the wild salmon dependent fishing enterprises and communities are facing major adjustments. Even though North Pacific wild salmon stocks are abundant at present, the large quantity of farm raised salmon and its method of sale and delivery reduce the price that can be obtained. There is some consideration in Alaska and Russia about starting aquaculture but it is recognized that the investment, organization, and technology may be significant hurdles (Link et al., 2003). Given the experience with salmon, there is also concern over the farming of halibut, sablefish, and cod becoming competitive with wild stock harvests.

13.5.5.6. Management regime

The US and Russian EEZs are the major management jurisdictions in the Bering Sea although the multilateral conventions for management of the "Donut Hole" fishery outside these boundaries also has an important role in fisheries management. Similarly, the Convention for a North Pacific Marine Science Organization and the Convention for the Conservation of Anadromous Stocks in the North Pacific Ocean provide frameworks for scientific exchange and cooperation. Even though the major activities covered by these conventions occur to the south of the ACIA boundary, the Wellington Convention for the Prohibition of Fishing with Large Driftnets constrains fisheries on the high seas with potential to intercept salmon of Russian and US origin as well to have negative bycatch effects on Dall's porpoise and some seabird species. Bilateral agreements, such as between Canada and the United States for salmon and halibut management and between Russia and Japan for salmon, also exist.

At the national level, the Magnuson-Stevens Fishery Conservation and Management Act is the prime legislation guiding fisheries management in federal waters. In Alaska, this means that all waters between 3 nm from the state's baselines and 200 nm is under federal jurisdiction. Other relationships exist, such as federal management for halibut in all waters due to the Convention between Canada and the United States for the Preservation of the Halibut Fishery of the Northern Pacific Ocean and Bering Sea, and Alaskan state jurisdiction (with federal oversight) over crabs as creatures of the continental shelf and salmon that are harvested within state waters (Miles et al., 1982a). The waters off Alaska constitute one of the nation's eight fishery management regions. This is administered by the regional office of

the National Marine Fisheries Service, with management decision-making taking place in the North Pacific Fishery Management Council – an advisory body to the regional director and thereby to the Secretary of Commerce. The federal regulations aim to develop a decision process that is comprehensive, transparent, and open to participation by all interested parties (NMFS, 2003b).

The main tools for fishery management are Fishery Management Plans that set out the rules and regulations for management of each species or species complexes. Under the current management approach, TAC is set on an annual basis in the Stock Assessment Fishery Evaluation process (e.g., NPFMC, 2002). As part of this process, ecosystem considerations are made explicit in the form of a chapter of the Stock Assessment Fishery Evaluation document that addresses ecosystem trends and relationships to fishing, as well as in the environmental assessments required in accordance with the National Environmental Policy Act. All meetings of the Council and its Advisory Committee and Scientific and Statistical Committee are open to the public. Thus, any interested party can observe and participate in deliberations of Plan Development Teams setting TACs.

The North Pacific Fishery Management Council has developed innovative approaches to management. Scientific advice is rigorously adhered to in the setting of TACs and conservative harvest limits are applied. A cap of two million tonnes has been set on total removals in the fishery even when allowable catches might be considerably higher. Bycatch is counted against TAC and target fisheries can be closed if the bycatch limit is reached before the target fishery TAC. Larger boats are required to carry and pay for one or more observers to gather scientific information about harvests. Species such as halibut, salmon, and herring are considered prohibited species in the groundfish and other non-target species fisheries. Finally, significant areas of the fishing grounds are closed to trawling to protect habitat necessary for other species, e.g., red king crab savings area (Witherell et al., 2000). In addition, much of the present work of the North Pacific Fishery Management Council is on developing spatially explicit relationships between fisheries and fish habitats under the Essential Fish Habitat Provisions of the Magnuson-Stevens Fishery Conservation and Management Act (NPFMC, 2003b). There is also a Council emphasis on rationalization of fisheries through share-based management systems such as the Individual Fishing Quota program for halibut and sablefish (and as proposed for Bering Sea and Aleutian Islands crabs) or through using a cooperative approach as for pollock under the American Fisheries Act, 1999.

In the EEZ of the Russian Far East, the issues and basic management system are similar to those in the Northeast Atlantic (see section 13.2.5) with the exception of the reciprocal fishing agreements. The regional administration is subject to central control for setting allocations and for Border Guard enforcement. From comments about the implementation of enforcement in

western Russia, it seems the US Coast Guard and the Border Guards have developed a more effective cooperation on enforcement in the Bering Sea, particularly with respect to the fishing zone boundary and high seas driftnet fishing. The scientific basis for setting allocations in Russia is similar to that of Alaska. Significant concerns have been expressed about how well such allocations are being followed and enforced (Velegjanin, 1999). Similarly, the role of the central as opposed to the regional fishery administrations in the setting and allocation of quotas is being challenged. For several years, significant proportions of the total allowable harvest are being auctioned to the highest bidders. This innovative effort has been controversial.

13.5.6. Variations in Bering Sea fisheries and socio-economic impacts: possible scenarios

The major changes in the commercial fisheries of the Bering Sea have been in the distribution of the harvests among nations and sub-nation user groups. Changes in the species composition of the catch due to changes in environmental conditions and fishing pressures have also affected those employed in the fishing industry and their communities. However, while the latter are of considerable interest in the present assessment, it is important to note that the adjustments to changing claims to jurisdiction in the Bering Sea have been extensive (Miles et al., 1982a). The enormous dislocation of fishing fleets from Japan and then the Soviet Union post-EEZ extension, shows that major adjustments can be made but with considerable hardship. Similarly, the response of the US fishing industry assisted by favorable government incentives shows how quickly it can respond to opportunity. The question thus is how fully occupied fisheries can respond to sustainable and precautionary management.

Fisheries in the Bering Sea are largely a post Second World War phenomenon in terms of the technology and scale of enterprise necessary to fish the inhospitable and enormous expanses of the remote Bering Sea shelf. With the developments in mothership operations and food processing technology came the development of new markets for species such as walleye pollock that despite being available in large quantities had not previously been considered a target species. Little is known about the fisheries ecosystem of the Bering Sea prior to the development of the intensive industrial-scale fisheries. Attention has been given to the early whaling activity in the North Pacific as this affected the more valuable and easier to harvest species. The effects of removing this biomass of whales on controls in the Bering Sea ecosystem is not clear (National Research Council, 1996) but cannot have been insignificant. The decline in the North Pacific whaling was offset by effort directed toward other areas, including the Southern Ocean. For communities where rending and processing occurred onshore, the displacement of effort meant the end of whaling as a source of employment and income.

Fisheries development after the Second World War tended to target the highest value species first. Despite efforts to develop sufficient scientific information and international management under the International Convention for High Sea Fisheries of the North Pacific Ocean, some stocks such as Pacific ocean perch and other longer-lived, high value species were overfished. The opportunity to fish on previously unfished stocks of very large size and extent resulted in significant employment and income benefits. With the development of coastal state management came the need to manage these large-scale fisheries properly. Most observers do not consider the harvests reported for the early period to be an accurate representation of catches. The valuable but limited joint scientific survey of stocks, performed by Canada, Japan, and the United States under the Convention, provides some information. This results in the period of record being extremely limited. Another factor is that the Bering Sea is a large, remote, and difficult area to characterize and monitor. Thus, the linking of scientific advice to fisheries management objectives has been a process of successive refinement. The ability to assess the range in natural variability in stock sizes is very imprecise and how the ecosystems function is only now being modeled with a significant degree of sophistication to begin to understand some of the issues involved (National Research Council, 2003).

Eight periods of alternating cold/warm sea temperatures are evident in the instrumental record. The extent to which these have altered population sizes and concentrations is difficult to establish for the reasons mentioned. Furthermore, population sizes may have been affected by high levels of fishing for some high value species, and low levels of fishing for species with low market value or with high levels of bycatch. Fishery management is generally thought to mediate for overfishing and to manage to maintain abundance of desired species. Since the mid- to late 1970s warmer temperatures and the associated patterns of atmospheric and sea surface circulation may have favored salmonids, winter-spawning flatfish, walleye pollock, Pacific cod, and Pacific halibut, and have been detrimental to capelin, Pacific herring, shrimps, and several species of large crab. Fisheries have developed on those species that are at high levels of abundance and left those whose abundance is low (NMFS, 2003b).

The US fishing industry in the Bering Sea survived changes in the relative abundance of particular species during the growth phase by, for example, shifting from crab fishing to walleye pollock fishing and Pacific cod fisheries. This has altered conditions for traditional crab processing ports in the Pribilof Islands but has contributed to the growth of groundfish processing in Dutch Harbor/Onalaska and Akutan. The question is what would happen to the industry under a pronounced shift to a coldwater period. Fisheries management is attempting to rationalize effort in these fisheries to increase efficiency, to reduce bycatch of prohibited

species, and to increase capture value through higher quality products and utilization rates. This tends to reduce flexibility of movement, as occurred when the domestic fisheries developed. There is little planning in place for how fishery management could operate in a transition between cold and warm regimes. For most of the groundfish species management under quotas, the expectation is that small or large year classes would be detected in the assessments and that quotas would rise and fall to prevent overfishing. For species with short lifespans this approach may be less effective, although high natural variability is considered by managers. For exceptionally long-lived species such as rockfish (*Sebastes* spp.), experience shows that very conservative harvest rates may need to be used and no-take marine reserves have been suggested as a tool to insure against loss of older highly productive fish.

This is an important issue, as is evident from the massive buildup of the red king crab fleet in the late 1970s to harvest anomalously large quantities of a Bristol Bay stock that subsequently crashed – probably due to recruitment failure following changes in environmental conditions. Additional effort entered the crab fleet with the strong stocks of snow crabs in the 1980s and 1990s. A sharp decline in these fisheries, again associated with changes in environmental conditions, caused severe problems for operators with high debt service and relatively few assets. These problems in the eastern Bering Sea crab fisheries provided an incentive to find other pot gear fishing opportunities and so other fixed gear operators in Pacific cod are now being squeezed by the entry of crab vessels into their traditional fisheries. This domino effect is highly predictable even if the underlying phenomena driving the process are not.

Warmer conditions are less favorable for pinnipeds. This appears to be an indirect food web effect rather than a direct effect through predation, although there may be interacting effects. This complex interaction between climate and pinniped survival has a pronounced effect on major commercial fisheries in the eastern Bering Sea under US jurisdiction. The spatial extent and timing of walleye pollock, Atka mackerel, and Pacific cod fisheries have been modified as a precautionary measure to protect Steller sea lions (National Research Council, 2003). In this way, changes in environmental conditions that result in effects on non-target species can be sufficiently significant in terms of the management of endangered and threatened species that they result in increased fishing costs and thus reduced profits.

The many subsistence fishing villages on the shores of the Bering Sea experience climate variability directly. The 65 CDQ communities in the eastern Bering Sea region have direct connections with climate variability through subsistence fishery activities and participation in the industrial fisheries through their partners. Industrial fisheries in the Bering Sea are dependent on large-scale shore-based processing plants that can operate, like the fishery itself, under difficult conditions. This is because catcher vessels that deliver to the shoreside plants must now operate further offshore because of the closed areas to buffer sea lion competition for prey. At-sea processors are more adaptable to changing environmental conditions because they can follow the fish and fishing conditions and can deliver to various ports.

Salmonids have well-documented aggregate north/south shifts in production under warm and cold periods (Beamish and Bouillon, 1993; Hare and Francis, 1995; Mantua et al., 1997). Although this does not explain all sources of variability it has been used successfully to gain a better management understanding. These trends are now being exacerbated by the decrease in market price following the decline in the Asian market and competition from farmed sources of Atlantic salmon. Even at high levels of abundance fishing for wild salmonids in the Bering Sea is at best marginal. This may force fundamental change in the structure and practices of salmon fishing. Also, extremely low returns to the Yukon River make survival of the Alaskan and Canadian indigenous peoples dependent on the abundance of migrating salmonids precarious. This has brought disaster relief in the form of federal and state loans and welfare programs. Recent studies (Kocan et al., 2001) suggest that the decline in Yukon stocks may be due to warmer environmental conditions and so beyond the control of fishery managers. The low levels of salmon have already resulted in renewed calls for reducing the salmon bycatch in Bering Sea trawl fisheries. Even though salmon bycatch rates have been reduced, more salmon are wanted by Yukon and other peoples. The trawl industry that has been pushed from low to higher bycatch areas due to measures for Steller sea lion protection has taken proactive real time measures to avoid salmon bycatch.

The location of the sea-ice edge and of the extent and timing of the melting of the sea ice as well as the development of the "cold pool" can have positive and negative effects on fisheries through their tendency to concentrate or disperse certain species or to contribute to increased levels of primary and secondary production within the Bering Sea ecosystem. Direct impacts on crab pot loss resulting from shifts in the position of the ice edge have been noted in the opilio fisheries in some cold years. The economic consequences of these types of variability are considered part of the risks of fishing in the Bering Sea. At present, it is possible to make only general comments about the effects of climate variability on fisheries in the Bering Sea from a socio-economic perspective. Better analyses require a better scientific understanding of ecosystem dynamics within the Bering Sea and a better ability to predict. A complicating factor is the difficulty of understanding the dynamics within the fisheries due to the very short period of record. Also, external market forces are currently affecting the value of the fisheries to a very significant extent and this may be more important than variability in landings or overall fish abundance.

At the industrial scale of fishing and processing that is characteristic of groundfish and crab fisheries in the Bering Sea, the social effects reflect broader economic trends. Lower prices and quantities generate fewer and less well paid jobs. However, high world market prices for species such as red king crab may offset declines in stocks when other sources of supply decrease (e.g., in Russian waters), or increase (e.g., red king crab in northern Norway). Rationalization through the economic system or fishery management systems may allow greater long-term stability with less overall investment in harvesting and processing. Fewer operators earning a greater return on investment are more likely to absorb swings in abundance due to changes in environmental or other conditions. It is difficult to assess impacts on consumers as the world trade in fisheries tends to find ways to satisfy market demands. However, impacts on fishery dependent communities and small family-owned enterprises can be devastating as the high costs of fishing may exceed the price available (Link et al., 2003). Having most assets tied up in ownership of a fishing vessel and gear, a limited entry area permit, and nowhere to sell is a formula for disaster. Many operations face bankruptcy and in communities with many such entities, there are few alternatives.

13.5.7. Ability to cope with change

Over the past few decades Bering Sea fisheries have been built around fairly consistent warm water species although there are some differences between the western and eastern Bering Sea. Coastal states have benefited more in recent years than distant water fishing nations. However, the management response to a transition to a cold phase has not been adequately considered nor has the response to continued warm periods. Changes to stocks in the western Bering Sea and projected stock dynamics in response to a moderate warming are explored in Table 13.2. Assuming a shift between a cold and warm regime in the mid-1970s, which for the Bering Sea is only ±1 °C (see section 13.5.4.2), could result in many effects and other coincident changes. For example: salmon increase in number but the world market price declines; groundfish abundance increases but the Asian market is weak owing to other economic factors; US snow crab stocks decline but Canadian stocks increase due to possible unfavorable or favorable environmental conditions.

A very small difference in ocean conditions can be detected as a cold or warm phase in the Bering Sea. Although a global climate change scenario for the Bering Sea *per se* does not exist, this shift between cold and warm periods provides some working hypotheses about what could be expected. At a minimum, it is likely that the conditions that have prevailed over the past few decades might constitute a baseline for slightly warmer conditions. Which means there is unlikely to be a resurgence of crab or shrimp populations or herring and capelin and other small pelagic species. The ecosystem would continue to be dominated by walleye pollock, Pacific cod, and flatfish. Walleye pollock juveniles may continue to occupy the role of coldwater forage fish. Salmonids would probably remain abundant in the aggregate in northern waters but in the south off British Columbia and Washington and Oregon stocks would decrease.

Socio-economically this baseline case would replicate the current system in terms of production of fish commodities. Through improvements in fishery management, it may be possible to increase the harvests of certain stocks by managing for recovery to levels of former abundance. However, it is just as likely that unforeseen events or interactions may result in management mistakes that offset such gains. Exploitation of underutilized species may be feasible to some degree. There may be some gains in catching the whole TAC due to changes in gear and fishing practices to generate lower bycatch rates. To attain increases in value added and utilization rates, it may be necessary to further rationalize the industry.

Additional factors to be included in the scenario of a continuation of prevailing conditions are declines in marine mammal and seabird populations. In some cases, fishery interactions, while modest and indirect, may justify further efforts to protect the numbers of seabirds and marine mammals under an adverse environmental regime, and such requirements may constrain fisheries more than would be the case if the stock was the sole interest of management. Similarly, environmental groups may change the level of performance that they expect fishery management to attain, i.e., no detectable impact standard or negligible effect standard and this would alter the management "field of play".

With continued warming, there is likely to be a range of sea temperatures that would continue to generate positive recruitment and growth scenarios for some of the warm water species (Table 13.2). This is likely to result in unfavorable conditions (i.e., increased predation) for pandalid shrimp and most crab species. If walleye pollock stocks increase, their impact as a predator on fish may also increase with unpredictable outcomes. Migration paths, timing of spawning, timing of the start of primary production, and species composition are very unlikely to remain the same. Similarly, reduced sea ice is likely to change the early spring ecosystem processes but greater surface exposure to winter storm conditions is likely to increase nutrient cycling and resuspension from shallower waters. To date, there are no credible published predictions of changes to fisheries north of the Bering Strait under a no or low sea ice scenario.

13.5.8. Concluding comments

In comparison to fisheries in other areas of the Arctic, commercial fisheries of the North Pacific, including the Sea of Okhostk and the Bering Sea, are relative newcomers. Commercial fishing for groundfish stocks other than Pacific halibut began in the Bering Sea in the 1950s by fleets from Japan and Russia and soon developed into

large-scale operations involving many nations. These fleets primarily harvested walleye pollock, Pacific cod, flatfish, sablefish, Atka mackerel, crab, herring, and salmon stocks. In the late 1970s, EEZs were established 200 nm seaward from the coast by Russia and the United States and fisheries management plans were established. By 1990, the distant water fleets were phased out of the eastern Bering Sea (i.e., the US EEZ). US fisheries off Alaska constitute more than half the landings and about half the value of national landings of fish and shellfish from federal waters. In the Russian EEZ, most catches are taken by domestic fleets with a decreasing proportion harvested under agreements with neighboring states.

Well-documented climate regime shifts occurred in the Bering Sea over the 20th century at roughly decadal time scales, alternating between warm and cool periods. A climate regime shift in the Bering Sea in 1977 changed the marine environment from a cool to a warm state. The warming-induced ecosystem shifts favored recruitment to herring stocks and enhanced productivity for Pacific cod, skates, flatfish, and non-crustacean invertebrates. The species composition of the benthic community changed from a crab-dominated assemblage to a more diverse mix of starfish, ascidians, and sponges. Pacific salmon production was found to be positively correlated with warmer temperatures. Consecutive strong year classes were established and historically high commercial catches were taken. Levels of walleye pollock biomass were low in the 1960s and 1970s (2 to 6 million t) but subsequently increased to levels greater than 10 million t and have remained large in most years since 1980.

Information from the contrast between the 1977 to 1989 warm period and the prior and subsequent cool periods (1960–1976 and 1989–2000) form the basis of the predicted response of the Bering Sea ecosystem to scenarios of future warming. Predictions include increased primary and secondary productivity with a greater carrying capacity, increased catches for species favored by a warm regime, poleward shifts in the distributions of some cold-water species, and possible negative effects on ice-associated species.

Walleye pollock is the major harvest species by volume and value, with Pacific cod, flatfish, salmon, and crabs constituting most of the rest. Total wholesale value for groundfish harvests in the eastern Bering Sea is approximately US$ 426 million, while the total primary processed value is approximately US$ 1.4 billion. The North Pacific fishing communities surrounding the Bering Sea are different from those of the North Atlantic. On the coast of the eastern Bering Sea there are some 65 communities with a total population of around 27 500 inhabitants, but these do not have a long history of fishing.

Fishery Management Plans are the main tool for fishery management in US waters. These set forth the rules and regulations for the management of each species or

species complexes. Under the current management approach, TACs are set on an annual basis in the Stock Assessment Fishery Evaluation process. Ecosystem considerations are explicitly made available at the time of the TAC setting process. The North Pacific Fishery Management Council has developed some fairly innovative approaches to management. In the EEZ of the Russian Far East, the regional administration is subject to central control for setting TAC allocations and for Border Guard enforcement.

The main changes over the years in the commercial fisheries of the Bering Sea have been in the distribution of the harvests among nations and sub-national user groups. There have been extensive adjustments to changing claims to jurisdiction in the Bering Sea. The tremendous dislocation of fishing fleets from Japan and Russia (then the Soviet Union) after the EEZ extension to 200 nm shows that major adjustments can be made but with considerable hardship. Similarly, the response of the US fishing industry, assisted by favorable government incentives, shows how quickly the fishery can respond to changed opportunities.

Eight periods of alternating cold/warm sea temperatures are evident in the instrumental record. Population sizes may have been affected by both high levels of fishing for some high-value species and low levels of fishing for species with low market value or with high levels of bycatch. Fishery management is generally intended to prevent overfishing and maintain the abundance of desired species. Since the mid- to late 1970s, warmer temperatures and associated atmospheric and sea surface circulation may have favored salmonids, winter-spawning flatfish, walleye pollock, Pacific cod, and Pacific halibut but have been detrimental to capelin, Pacific herring, shrimps, and several species of large crab. Fisheries are fully developed on those species that are at high levels of abundance, but have essentially ceased on those whose abundance is low. The last few decades of Bering Sea fisheries have been built around species that consistently favor warm water. However, there are some contradictions between the western and eastern Bering Sea. There is no question that coastal states have benefited more in recent years than distant water fishing nations. However, the management response to a transition to a cold phase has not been adequately considered, nor has it for the opposite, i.e., continued prevailing warm conditions.

Previous sections of this chapter have demonstrated that a very small difference in ocean environmental conditions can be detected as a cold or warm phase in the Bering Sea. While there is not a global climate change scenario for the Bering Sea per se, this shift between cold and warm periods does provide a basis for some working hypotheses about what to expect in the area in future. At a minimum, it is likely that the conditions which have prevailed over the last few decades might constitute a baseline for slightly warmer conditions. Therefore, there is not likely to be a resurgence of crab or shrimp populations, or herring and

capelin and other small pelagic fish species. The ecosystem is likely to continue to be dominated by walleye pollock, Pacific cod, and flatfish. Walleye pollock juveniles are likely to continue their role as cold-water forage fish. Salmonids are likely to remain abundant in the aggregate in northern waters, but south off British Columbia and Washington and Oregon stock abundance would be depressed.

Socio-economically this baseline case would replicate the current system in terms of production of fish commodities. Through improvements in fisheries management, it may be possible to increase harvests of certain stocks by managing for recovery to levels of former abundance. However, it is probably just as likely that unforeseen events or interactions may produce management mistakes that offset such gains in a dynamic ocean system. Exploitation of underutilized species may be feasible to some degree. Some gains in catching the whole TAC might be possible due to improvements in gear and fishing practices to lower bycatch rates. In order to attain increases in value added and in utilization rates, the industry may need to be further rationalized.

Under a continued warming scenario, it is very likely that there could be a range of temperatures that would continue to generate positive recruitment and growth scenarios for some of the warm advantaged species. These conditions would be negative for pandalid shrimp and most crab species. If walleye pollock stocks increase, their impact as a predator on fish may also increase with unpredictable outcomes. It is very unlikely that migration paths, timing of spawning, timing of start of primary production, and composition of species would remain the same. Similarly, loss of sea ice may result in changes to the early spring bloom and associated ecosystem processes, however greater surface exposure to winter storm conditions might increase nutrient circulation and resuspension in shallower waters. To date, there are no credible published data on what could happen in the waters north of the Bering Strait with respect to fisheries under a change to a significantly warmer climate.

13.6. Synthesis and key findings

Modeling experiments show that it is not easy to project changes in climate due to forces, which can and have been measured and even monitored on a regular basis for considerable periods of time and are the data upon which such models are built. The main reason being that major natural events occur over time scales greater than decades or even centuries and the period of regular monitoring of potentially important forcing events is relatively short. Also, current climate models do not include scenarios for ocean temperatures, watermass mixing, upwelling, and other relevant ocean variables such as primary and secondary production, neither globally nor regionally. Thus, it is not possible to predict the effects of climate change on marine fish stocks with any degree of certainty and so the eventual socio-economic consequences of these effects for arctic fisheries.

Nevertheless, and despite these difficulties, the scientific community should still rise to the challenge of predicting reactions of marine stocks in or near the Arctic to climate change, basing initial studies on past records of apparent interactions, however imperfect and inconclusive. It is on such bases – and such bases only – that effective future research can and should be planned and undertaken.

Commercial fisheries in arctic regions are based on a number of species belonging to physically different ecosystems. The dynamics of many of these ecosystems are not well understood. This adds a significant degree of uncertainty to attempts to predict the response of individual species and stocks to climate change. Indeed, to date it has been difficult to identify the relative importance of fishing and the environment on changes in fish populations and biology. Moreover, current fish populations differ in abundance and biology from past populations due to anthropogenic effects (i.e., exploitation rates). As a result it is unclear whether current populations will respond to climate change as they may have done in the past.

Nevertheless, it does appear likely that a moderate warming will improve the conditions for some of the most important commercial fish stocks, as well as for aquaculture. This is most likely to be due to enhanced levels of primary and secondary production resulting from reduced sea-ice cover and more extensive habitat areas for subarctic species such as cod and herring. Global warming is also likely to induce an ecosystem regime shift in some areas, resulting in a very different species composition. Changing environmental conditions are likely to be deleterious for some species and beneficial for others. Thus, relative population sizes, fish growth rates, and spatial distributions of fish stocks are likely to change (see Table 9.11). This will result in the need for adjustments in the commercial fisheries. However, unless there is a major climatic change over a very short period, these adjustments are likely to be relatively minor and are unlikely to entail significant economic and social costs.

The total effect of climate change on fish stocks is probably going to be of less importance than the effects of fisheries policies and their enforcement. The significant factor in determining the future of fisheries is sound resource management practices, which in large part depend upon the properties and effectiveness of resource management regimes. All arctic countries are currently making efforts to implement management strategies based on precautionary approaches, with increasing emphasis on ecosystem characteristics, effects of climate changes, and including risk and uncertainty analyses in decision-making. Ongoing adjustments to management regimes are likely to enhance the ability of societies to adapt to the effects of climate change.

The economic and social impacts of altered environmental conditions depend on the ability of the social

structures involved, including the fisheries management system, to generate the necessary adaptations to the changes. It is unlikely that the impact of the climate change projected for the 21st century (see Chapter 4) on arctic fisheries will have significant long-term economic or social impacts at a national level. Some arctic regions, especially those very dependent on fisheries or marine mammals and birds in direct competition with a fishery may, however, be greatly affected. Local communities in the north are exposed to a number of forces of change. Economic marginalization, depopulation, globalization-related factors, and public policies in the different countries are very likely to have a stronger impact on the future development of northern communities than climate change, at least over the next few decades.

This chapter considers the possible effects of projected climate change on four major ecosystems: the Northeast Atlantic (Barents Sea), the central North Atlantic (Iceland/Greenland), Northeast Canada (Newfoundland/Labrador), and the North Pacific (Bering Sea). There are substantial differences between these regions in that the Barents Sea and Icelandic waters are of a subarctic/temperate type, while the arctic influence is much greater in Greenland waters, the waters off northeast Canada, and the Bering Sea. It follows, therefore, that climate change need not affect these areas in the same or a similar manner. Also, the length of useful time series on past environmental variability and associated changes in hydrobiological conditions, fish abundance, and migrations varies greatly among regions. Finally, there are differences in species interactions and variable fishing pressure, which must also be considered.

Owing to heavy fishing pressure and stock depletions, the Barents Sea, Icelandic waters, and possibly also the Bering Sea could, through more efficient management, yield larger catches of many fish species. For that to happen research must increase, and more cautious management strategies must be developed and enforced. However, a moderate warming could enhance the rebuilding of stocks and could also result in higher sustainable yields of most stocks, among others, through enlarged distribution areas and increased availability of food in general. On the other hand, warming could also cause fish stocks to change their migratory range and area of distribution. This could (as history has shown) trigger conflict among nations over distribution of fishing opportunities and would require tough negotiations to generate viable solutions regarding international cooperation in fisheries management.

The waters around Greenland and off northeast Canada are very different from the above. These regions are more arctic in nature. Greenland appears unable to support subarctic species such as cod and herring except during warm periods. Examples from the 20th century prove this point. For example, there were no cod in the first two and a half decades, but a large local self-sustaining cod stock from 1930 until the late 1960s, apparently initiated by larval and 0-group drift from Iceland. If current climate conditions remain unchanged little change is likely around Greenland. On the other hand, a "moderate warming" such as that between 1920 and the late 1960s is likely to result in dramatic changes in species composition – a scenario where cod would play the major role. The northeast Canadian case is an extreme example of a situation where a stock of Atlantic cod (the so-called "northern" cod), which had sustained a large fishery for at least two centuries, is suddenly gone. Opinion differs as to how this has happened; most people believe that the decline was due entirely to overfishing, whereas others think that adverse environmental factors were significant contributors. In the present situation, however, the northern cod stock is so depleted that it is very likely to take decades to rebuild – even under the conditions of a warming climate.

An evaluation of what could happen to marine fisheries and aquaculture in the Arctic should the climate warm by more than 1 to 3 ºC is not attempted in the present assessment. This is beyond the range of available data and would be of limited value. In general terms, however, it is likely that at least some of the ecosystems would experience reductions in present-day commercial stocks which might be replaced partially or in full by species from warmer waters.

13.7. Research recommendations

Past experience shows that marine living resources are not unlimited and must be harvested with caution. Although management practices have improved in recent decades, the present situation still leaves much room for improvement. More and better research is required to fill this gap.

1. Present monitoring of the physical and biological marine environment must be continued and in many cases increased. Basic research is often considered a burden, but is a prerequisite for understanding biological processes. Modern technology enables the automation of many of the time consuming tasks previously conducted from expensive research vessels. For example, buoys can now be deployed in strategic locations on land and at sea for continuous measurement of many variables required in marine biological studies. The monitoring of commercial stocks must also continue, applying new technologies as these become available. There is a general shortage of ship time for sea-based work. Administrators (governments) are often unaware of this, also that despite computers enabling more extensive and deeper analyses of existing datasets, people are still required to operate and program the computers.

2. Although the modeling of marine processes, particularly the modeling of climate variability, is still in its infancy, such work is the key to increasing understanding of the effects of the projected climate change scenarios (see Chapter 4). The devel-

opment of regional applications is particularly important. Regional effects might differ substantially from those considered average global effects. In order to relate physical changes in the atmosphere and oceans to changes within specific ecosystems, the modeling of regional effects is essential. Current fisheries management models are based on general assumptions of constant environmental factors. The use of ecosystem-based approaches for fisheries management will require that physical and biological factors that do not directly affect the target species are also taken into account.

3. It is extremely difficult to estimate the economic consequences of climate change on the world fisheries or the fisheries for any given region. It is important to invest in the development of better methods for examining the economic and social consequences of climate change, at both the global and regional level, and at the national and local level.

Summary

The boreal region covers about 17% of global land area, and the arctic nations together contain about 31% of the global forest (non-boreal and boreal). The boreal forest is affected by and also contributes to climate change through its influence on the carbon cycle and albedo. Boreal forests influence global levels of atmospheric carbon dioxide and other greenhouse gases by taking up carbon dioxide in growth, storing carbon in live and dead plant matter, and releasing carbon through decomposition of dead organic matter, live plant and animal respiration, and combustion during fire. Human management influences on carbon uptake and storage include the rearrangement of forest age classes through timber harvest or wildfire suppression, selection of tree species, fertilization, and thinning regimes. The combined effect of all management actions can either enhance or reduce carbon uptake and storage.

Agriculture has existed in the Arctic as defined in this chapter for well over a millennium, and today consists of a mixture of commercial agriculture on several thousand farms and widespread subsistence agriculture. Potatoes and forage are characteristic crops of the cooler areas, and grains and oilseed crops are restricted to areas with the warmest growing seasons. The main livestock are dairy cattle and sheep, which have been declining, and diversified livestock such as bison or other native animals, which have generally been increasing in commercial operations. The five ACIA-designated models all project rising temperatures that are very likely to enable crop production to advance northward throughout the century, with some crops now suitable only for the warmer parts of the boreal region becoming suitable as far north as the Arctic Circle. The average annual yield of farms is likely to increase at the lower levels of warming due to climate suitability for higher-yielding crop varieties and lower probabilities of low temperatures limiting growth. However, in the warmest areas, increased heat units during the growing season are very likely to cause a slight decrease in yields since warmer temperatures can speed crop development and thereby reduce the amount of time organic matter accumulates. Under the ACIA-designated model projections, water deficits are very likely to increase or appear in most of the boreal region. By the end of the 21st century, unless irrigation is practiced, water stress is very likely to reduce crop yields. Water limitation is very likely to become more important than temperature limitations for many crops in much of the region. Overall, negative effects are unlikely to be stronger than positive effects. Lack of infrastructure is likely to remain a major limiting factor for commercial agricultural development in the boreal region in the near future. Even under model-projected levels of climate change, government policies regarding agriculture and trade will still have a very large, and perhaps decisive, influence on the occurrence and rate of agricultural development in the north.

Understanding the condition or character of the forest resource system that climate change affects is crucial in assessing forests and land management. Russia has made commitments to management of carbon stocks that are of global interest because of the amounts involved. Fire and insect disturbance at very large scales have generated resource management challenges in Canada. A large proportion of Alaska is managed as strict nature reserves and as resource lands for biodiversity and ecosystem services. Large forest disturbances associated with climate change have occurred in Alaska, disrupting ecosystems and imposing direct costs, but the large area of reserves improves the ultimate prospects of species surviving potential future climate change. In highly managed forests of Finland, Sweden, and Norway, forests are generally managed effectively and are increasing in volume, but the prospect of climate change puts at risk human expectations of specific future resource returns. In Iceland, temperature increases have improved tree growth at a time of a large afforestation program designed to increase forest land cover and sequester carbon.

About 6000 years BP (the end of the postglacial thermal maximum), radial growth of larch trees on the Taymir Peninsula of Russia surpassed the average of the last two millennia by 1.5 to 1.6 times. Tree growth and warm-season temperature have irregularly decreased in northernmost Eurasia and North America from the end of the postglacial thermal maximum through the end of the 20th century. Long-term tree-ring chronologies from Russia, Scandinavia, and North America record the widespread occurrence of a Medieval Warm Period about 1000 years BP, a colder Little Ice Age ending about 150 years ago, and more recent warming. Recent decades were the warmest in a millennium or more at some locations. Temperature and tree growth records generally change at the same time and in the same direction across much of the Arctic and subarctic. However, intensified air-mass circulation associated with a warmer climate has introduced a stronger flow of warm air into specific regions of the Arctic and enhanced the return flow of cold air out of the Arctic in other regions. Temperature and tree-growth trends are correlated but opposite in sign in these contrasting regions.

Between 9000 and 7000 years BP, trees occurred in at least small groups in what is now treeless tundra nearly to the arctic coastline throughout northern Russia. Around 6000 years BP, the northern treeline on the Taymir Peninsula (currently the farthest north in the world) was at least 150 km further north than at present. During the period of maximum forest advance, mean July temperature in northern Russia is estimated to have been 2.5 to 7.0 °C higher than the modern mean. This record of past forest advance suggests that there is a solid basis for projecting similar treeline change under climate change producing similar temperature increases. It also suggests that the components of ecosystems present today have the capacity to respond and adjust to such climate fluctuations. The

greatest retreat of forest and expansion of tundra occurred between 4000 and 3000 years BP. In northeast Canada, the black spruce forest limit has remained stable for the past 2000 to 3000 years. In recent decades, milder winters have permitted stems that were restricted to snow height by cold and snow abrasion to emerge in upright form, and future climate projected by the ACIA-designated models would permit viable seed production, which is likely to result in infilling of the patchy forest–tundra border and possibly begin seed rain onto the tundra. In the Polar Ural Mountains, larch reproduction is associated with warm weather, and newly established trees have measurably expanded forest cover during the 20th century, although there is a time lag between climate warming and upslope treeline movement.

Across the boreal forest, warmer temperatures in the last several decades have either improved or decreased tree growth, depending on species, site type, and region. Some tree-growth declines are large in magnitude and have been detected at different points across a wide area, although the total extent has not been delineated. Temperature-induced drought stress has been identified as the cause of reduced growth in some areas, but other declines are not currently explained. Reduced growth in years with high temperatures is common in treeline white spruce in western North America, suggesting reduced potential for treeline movement under a warming climate. Tree growth is increasing in some locations, generally where moisture and nutrients are not limiting, such as in the boreal regions of Europe and eastern North America. The five ACIA-designated models project climates that empirical relationships suggest are very unlikely to allow the growth of commercially valuable white spruce types and widespread black spruce types in major parts of Alaska and probably western boreal Canada. The models project climates that are very likely to increase forest growth significantly on the Taymir Peninsula. The upper range of the model projections represents climates that may cross ecological thresholds, and it is possible that novel ecosystems could result, as during major periods of global climate change in the past.

Large-scale forest fires and outbreaks of tree-killing insects are characteristic of the boreal forest, are triggered by warm weather, and promote many important ecological processes. On a global basis, atmospheric carbon equal to 15 to 30% of annual emissions from fossil fuels and industrial activities is taken up annually and stored in the terrestrial carbon sink. Between 1981 and 1999, it is estimated that the three major factors affecting the terrestrial carbon sink were biomass carbon gains in the Eurasian boreal region and North American temperate forests, and losses in areas of the Canadian boreal forest. Particular characteristics of forest disturbance by fire and insects, such as rate, timing, and pattern of disturbance, are crucial factors in determining the net uptake or release of carbon by forests. The evidence necessary to establish a specific climate change effect on disturbance includes a greater frequency of fire or insect outbreaks, more extensive areas of tree mortality, and more intense disturbance resulting in higher average levels of tree death or severity of burning. Some elements of the record of recent boreal forest disturbance are consistent with this profile of climate change influence, especially forest fires in some parts of Russia, Canada, and Alaska and insect disturbances in North America.

Carbon uptake and release at the stand level in boreal forests is strongly influenced by the interaction of nitrogen, water, and temperature influences on forest litter quality and decomposition. Warmer forest-soil temperatures that occur following the death of a forest canopy due to disturbance increase the rate of organic litter breakdown, and thus the release of elements for new plant growth (carbon uptake). The most likely mechanism for significant short-term change in boreal carbon cycling as a result of climate change is the control of species composition caused by disturbance regimes. Successional outcomes from disturbance have different effects on carbon cycling especially because of the higher level and availability of nutrient elements (and thus decomposition) in organic litter from broadleaf trees compared to conifers. Net global land-use and land-cover change, especially aggregate increases or decreases in the area of forest land, may be the most important factor influencing the terrestrial sink of carbon. When water and nitrogen remain available at the higher growth rates typical of enhanced carbon dioxide environments, further carbon uptake occurs. Broadleaf litter produced under elevated carbon dioxide conditions is lower in quality (less easily decomposed) than regular litter because of lower nitrogen concentration, but quality of conifer litter in elevated carbon dioxide environments may not be as affected.

Different crop species and even varieties of the same species can exhibit substantial variability in sensitivity to ultraviolet-B (UV-B) radiation. In susceptible plants, UV-B radiation causes gross disruption of photosynthesis, and may inhibit plant cell division. Determining the magnitude of the effect of elevated UV-B radiation levels is difficult, because interactions with other environmental factors, such as temperature and water supply, affect crop reactions and overall growth. Damage by UV-B radiation is likely to accumulate over the years in trees. Evergreens receive a uniquely high UV radiation dose in the late winter, early spring, and at the beginning of the growing season because they retain vulnerable leaf structures during this period of maximum seasonal UV-B radiation exposure, which is amplified by reflectance from snow cover. Exposure to enhanced levels of UV-B radiation induces changes in the anatomy of needles on mature Scots pine similar to characteristics that enhance drought resistance. UV-B radiation plays an important role in the formation of secondary chemicals in birch trees at higher latitudes. Secondary plant chemicals released by birch exposed to increased UV-B radiation levels might stimulate its herbivore resistance.

14.1. Introduction

The Arctic has been defined in somewhat different ways in various studies, reports, and assessments, based primarily on the purpose of the project. While the most restrictive definitions limit the Arctic to treeless tundra, snow, and ice in the high latitudes, most definitions of the Arctic encompass some elements of the boreal forest. The definition used by the Arctic Monitoring and Assessment Programme (AMAP, 1997; see section 8.1.1, Fig. 8.2), for example, includes the productive boreal forests of northwest Canada and Alaska, but includes mostly marginal treeline forest and woodland in eastern Canada. Permafrost-free forests in the northern portion of the Nordic countries are within the AMAP-defined Arctic, but across central and eastern Siberia, the boundary follows the margin of sparse northern taiga and forest–tundra. This chapter focuses on the northernmost portion of the boreal forest region, but broadens consideration of the subject for two important reasons. First, many elements of the boreal forest are best understood as a whole (e.g., the gradients of changing tree responses to the environment from south to north), and this chapter includes an extensive and well studied Siberian transect that uses such an approach. Second, the five scenarios of climate change generated by the ACIA-designated models (section 4.4) project temperatures within the Arctic that today only occur in the boreal forest far to the south. If temperature increases of a magnitude similar to those projected by these models actually occur, the nearest analogues of climate (and eventually ecosystems) that would exist in the Arctic are those of more southerly boreal forest regions.

Sections 14.2 and 14.3 describe forest characteristics across the northern boreal forest to provide the context for understanding the importance of recent climate-related changes in the region and potential future change. Section 14.4 provides an overview of the climate scenarios generated by the ACIA-designated models and describes how the scenarios were used in different aspects of the assessment.

While many factors affect agriculture in the far north (e.g., changing markets, social trends, and national and international policies), section 14.5 focuses on the climate-sensitive aspects of crop production systems that would be affected under the scenarios of future climate, focusing on climate stations representative of areas with agricultural production or potential. Section 14.3 also considers the challenges that climate change poses for land management. Tree rings are one of the most important sources of information about past climates, especially in the sparsely populated far north, and section 14.6 reviews the record of climate and tree rings across the Arctic and northern boreal region.

Section 14.7 presents new information about the direct effects of climate on tree growth in the northern boreal forest, in both the distant and more recent past, and uses scenarios generated by the ACIA-designated models to

project how climate change may affect the growth of selected tree species during the 21st century. Section 14.8 identifies key climate controls on large-scale population increases in insects that damage trees, and provides some recent evidence of these effects.

Forest fire is another major indirect effect of climate on the status of forests in the far north. Section 14.9 examines some of the climate-sensitive aspects of fire and possible future fire conditions and effects. The climate-related changes in growth, insect-caused tree death or reductions in tree growth, and fire are major factors that control the uptake and storage of atmospheric carbon (section 14.10). The implications of future climate change for forest distribution are briefly considered in section 14.11. Finally, section 14.12 summarizes some recently published information on the effects of increased UV-B radiation levels on boreal forest species, and section 14.13 reviews critical research needs.

14.2. The boreal forest: importance and relationship to climate

14.2.1. Global importance

The boreal region covers about 17% of the terrestrial area of the earth (Bonan et al., 1992), with a broad zone of forest in a continuous distribution across the Eurasian and North American landmasses. The boreal forest is defined as a belt of forest south of the tundra characterized by a small number of coniferous species including spruce, larch, pine, and fir and a limited number of broad-leaved species, primarily birch and poplar (see Appendix D for common and scientific names of tree and other woody species mentioned in this chapter). At the landscape scale, conifers dominate the boreal forest, although broad-leaved trees can be locally dominant. Forest and woodland in the arctic nations (excluding

Table 14.1. Total forest area in arctic nations and percentage of global forest area (Smith W. et al., 2001; US Forest Service, www.fs.fed.us/r10/spf/facts/spffact.htm).

	Total forest area (10^6 ha)	% of global forest area

Arctic nation total	1456.2	38.3
World total	3800	100

[a]"forest" category (FAO, 2002); [b]"boreal forest" category (Labau and van Hees, 1990)

Denmark), most of which is boreal forest, represent about 1.5 billion hectares (ha) of the total global forest area of 3.8 billion ha (in 2000), or about 38% of global forest area (FAO, 2001; Table 14.1). Russian forests (excluding woodlands), the vast majority of which are boreal, represent 22.4% of the global total, by far the largest proportion of any nation in the world (Table 14.1). Two of the remaining three countries with the largest percentage of global forest area (Canada and the United States) are also arctic nations.

This chapter focuses on the northern portion of the boreal forest, but many aspects of the topic must be considered from a broader perspective. The boreal forest contains trees growing at the highest latitude on earth, and along its northern margin it merges into the circumpolar tundra. The boreal region is the northernmost part of the world where agricultural crops are produced regularly on a significant scale and where a settled agricultural way of life has historical continuity.

The boreal forests of North America and Eurasia share some plant and animal species and display a number of other similarities. The boreal forests of Russia and especially Siberia are often referred to as the taiga, an indigenous term meaning "little sticks". The term taiga is equivalent to the true boreal forest.

The boreal forest is both affected by and contributes to climate change: both topics are examined in this chapter. Globally, the existence of large areas of boreal forest cover has a significant effect on the radiative balance of the planet (Bonan et al., 1992). The rough-textured, dark surface of land covered with boreal forest canopy intercepts and absorbs a high proportion of solar radiation, converting it to heat (Bonan et al., 1992). In contrast, the smooth, snow-covered surface of the tundra is highly reflective. In high-latitude regions where snow covers the ground for half of the year or more, the albedo effect of tundra versus boreal forest cover is magnified. Future expansion of the forest into present-day tundra regions resulting from a warming climate would thus amplify the warming further.

Another important influence of the global boreal forest on climate is its influence on levels of atmospheric carbon dioxide (CO_2) and other greenhouse gases (GHGs). Boreal forests take up CO_2 through photosynthesis, and store carbon in live and dead plant matter, including substantial long-term accumulations in large tree boles and in soil. Forests release CO_2 to the atmosphere through decomposition of dead organic matter, live plant and animal respiration, and combustion that takes place during fires. Both natural (e.g., fire) and anthropogenic (e.g., timber removal) disturbances are important influences on the boreal forest. An ecosystem disturbance is defined as a change in state or condition that disrupts the way in which the system has been functioning (photosynthesis, water regulation, etc.), causing it to reinitiate successional development. Disturbances vary by cause, rate, intensity, extent, timing, frequency, and duration.

Management-related factors influence carbon uptake and storage in the form of tree mass. These management practices include the rearrangement of forest age classes by timber harvest or suppression of wildfires, selection of tree species, fertilization, and thinning regimes. The combined effect of all management actions can either enhance or reduce carbon uptake and storage. For example, across the Russian boreal region, for many years after logging the forests that regrow take up less atmospheric CO_2 than nearby old-growth forests (Schulze et al., 1999). In the Boreal Cordilleran ecozone of Canada (see Wiken, 1986 for definition), it is estimated that total suppression of natural disturbances and their complete replacement by harvesting for maximum sustainable yield would increase carbon storage in soils and wood products over a period of a century or two (Price et al., 1997). Direct climate effects that increase or decrease tree growth in unmanaged natural forests also influence short-term uptake of atmospheric carbon.

The boreal forest and northern tundra together contain 40% of global reactive (readily decomposable to CO_2, methane, water, and mineral nutrients) soil carbon, an amount similar to the amount of carbon held in the atmosphere (McGuire et al., 1995b; Melillo et al., 1993). The extensive boreal forest plains of northeast Europe, western Siberia, and central and eastern North America that are within or immediately south of the discontinuous permafrost region occupy the zone of maximum carbon storage in soil organic matter on the earth. Climate change, interacting with human use and management of boreal forest, northern agricultural, and tundra ecosystems, would enhance the decomposition of carbon stored in soil organic matter and its subsequent release into the atmosphere, thus compounding climate change caused by anthropogenic GHG emissions.

The boreal forest is one of the most intact major vegetation regions of the earth, but in some areas boreal forest has been extensively converted to other land uses or severely damaged by air pollution (e.g., in Iceland and particular areas of Russia, respectively). Boreal forests in Finland, Sweden, Norway, and parts of Canada are generally intensively managed for timber production, and in such intensively managed stands, tree age structure, tree species, and spacing are controlled (section 14.3.4). However, huge areas of central and eastern Siberia and northwestern North America represent the most extensive remaining areas of natural forest on the planet (Bryant et al., 1997). Not all natural boreal forests consist of older trees: large areas are burned or subject to insect-caused tree mortality annually. Climatic factors, especially prolonged periods of warm weather, often create the conditions that result in fire and insect disturbances in boreal forests. The boreal forest is subject to rapid changes causing long-term consequences as a result of these climate-related effects.

The boreal forest is the breeding zone for a huge influx of migratory forest birds that perform many important roles (e.g., insect consumption, seed dispersal) in the

boreal region and in other forests of the world during migration and winter residence in the south. Climate affects the population level of these migratory birds and their food resources. Climate-associated processes also determine the amount and quality of forest habitat available to migratory birds.

From 1981 to 1999, three regions of the world primarily affected the terrestrial carbon sink, which takes up and stores atmospheric carbon equivalent to 15 to 30% of annual global emissions from fossil fuel combustion and industrial activities (Myneni et al., 2001). The majority of the net terrestrial carbon change came from biomass carbon gains in the Eurasian boreal region and North American temperate forests, and carbon losses from some Canadian boreal forests. Some of the terrestrial biomass change was a response to direct and indirect climate effects. However, human use and management of the boreal forest was an important factor as well, and could be a significant future contributor to human management of the carbon cycle. Certain forest biomass carbon sinks can be used to meet national commitments to reduce GHG emissions under the Kyoto Protocol of the Framework Convention on Climate Change. Land and resource managers in the Arctic and boreal regions are interested in potential "carbon cropping", which might involve payments from organizations wishing to sustain or enhance carbon storage (Bader, 2004). Mechanisms to place values on the various carbon transfers are not fully in place. However, if effective, exchangeable systems of placing values on transfers of carbon are adopted at an international level, boreal forests could potentially generate a flow of wealth into arctic and subarctic regions from other parts of the world for boreal forest and land management treatments, offsets for emissions elsewhere, or policies designed to store or retain carbon.

Uncertainties remain about the influence of the boreal forest on each of the key processes that determine global carbon balance. For example, the uptake of atmospheric CO_2 by tree and other plant growth may either increase or decrease with increasing temperature, depending on the species, the geographic region where the growth occurs, the range of the temperature increase, and other climate factors such as precipitation that are likely to change in a changing climate. However, there has been substantial recent progress in understanding the response of elements of the boreal system to temperature. Across the boreal regions, a first generation of studies, models, databases, and measurements have provided a significantly better understanding of one of the most extensive and important vegetation types on earth. Continued and expanded data collection from research and management activities will provide a reasonable basis for determining the net contribution of the boreal forest to GHG balance and climate, the further changes a warming climate would induce in the boreal forest, and the agricultural and forest management opportunities available to the region in the future.

14.2.2. Arctic importance

Trees occur on only a small proportion of the land surface within the Arctic as defined in this chapter. Even so, forests and woodlands are important on a regional basis within the Arctic for several reasons. Where trees do occur, they serve as indicators of more productive terrestrial ecosystems with longer growing seasons than treeless tundra. Trees, even when present in small numbers on the arctic landscape, offer resources to arctic residents for a variety of uses. Finally, some areas of full-canopy forest within the Arctic are generally the most productive natural systems within the political jurisdiction where they occur (e.g., the galley forests along rivers that extend into the tundra in the northern Yukon and Northwest Territories in Canada). Specific reasons for the importance of boreal forest and agriculture in the Arctic include the following:

- Portions of the boreal forest devoted to forest products production are major contributors to the national economies of some arctic nations. Although the current zone of optimum climate for boreal forest growth is in the middle or southern boreal region, nearly all scenarios of climate change place the climatically optimum growth region within the present-day Arctic within a century or so.
- Residents of the boreal region depend on the products and resources of the forest for a variety of ways of life, including traditional ways of life.
- The major rivers of the boreal region transport large volumes of wood into the Arctic (Eggertsson, 1994; Ott et al., 2001), and this wood resource supports ecosystems that decompose the wood and feed organisms in rivers, oceans, and beaches. Climate change is very likely to affect all the processes in this system, including tree growth, erosion, river transport, and wood decay.
- Wood transported into the Arctic was an important resource for people in a naturally treeless environment during prehistoric times (Alix, 2001) and is still a useful and valued resource for many arctic residents today.
- The boreal forest collects, modifies, and distributes much of the freshwater that enters the Arctic Basin (see sections 6.8 and 8.2), and changes in boreal forests resulting from climate change would certainly affect many of these important functions.
- Portions of the boreal forest region have experienced some of the greatest temperature increases reported during the 20th century, and the responses of the forest system and the societal consequences in the region provide lessons that may be useful to other regions that could eventually experience similar change.
- Recent temperature increases in the boreal region have increased the frequency of occurrence of critical temperature thresholds for the production of agricultural crops currently grown in the region. Possible future temperature increases almost cer-

tainly would increase the land area on which crops could be produced successfully, and are very likely to increase the variety of agricultural crops that could be grown.

14.2.3. Climatic features

The boreal region is often assumed to be a zone of homogenous climate, but climate across the region is actually surprisingly diverse. During the long summer days, interior continental locations under persistent high-pressure systems experience hot weather that facilitates extensive forest fires frequently exceeding 100 000 ha. In maritime portions of the boreal region affected by air masses that originate over the North Atlantic, North Pacific, or Arctic Oceans, summer daily maximum temperatures are on average cooler than interior locations and seldom reach the high temperatures experienced at locations further inland.

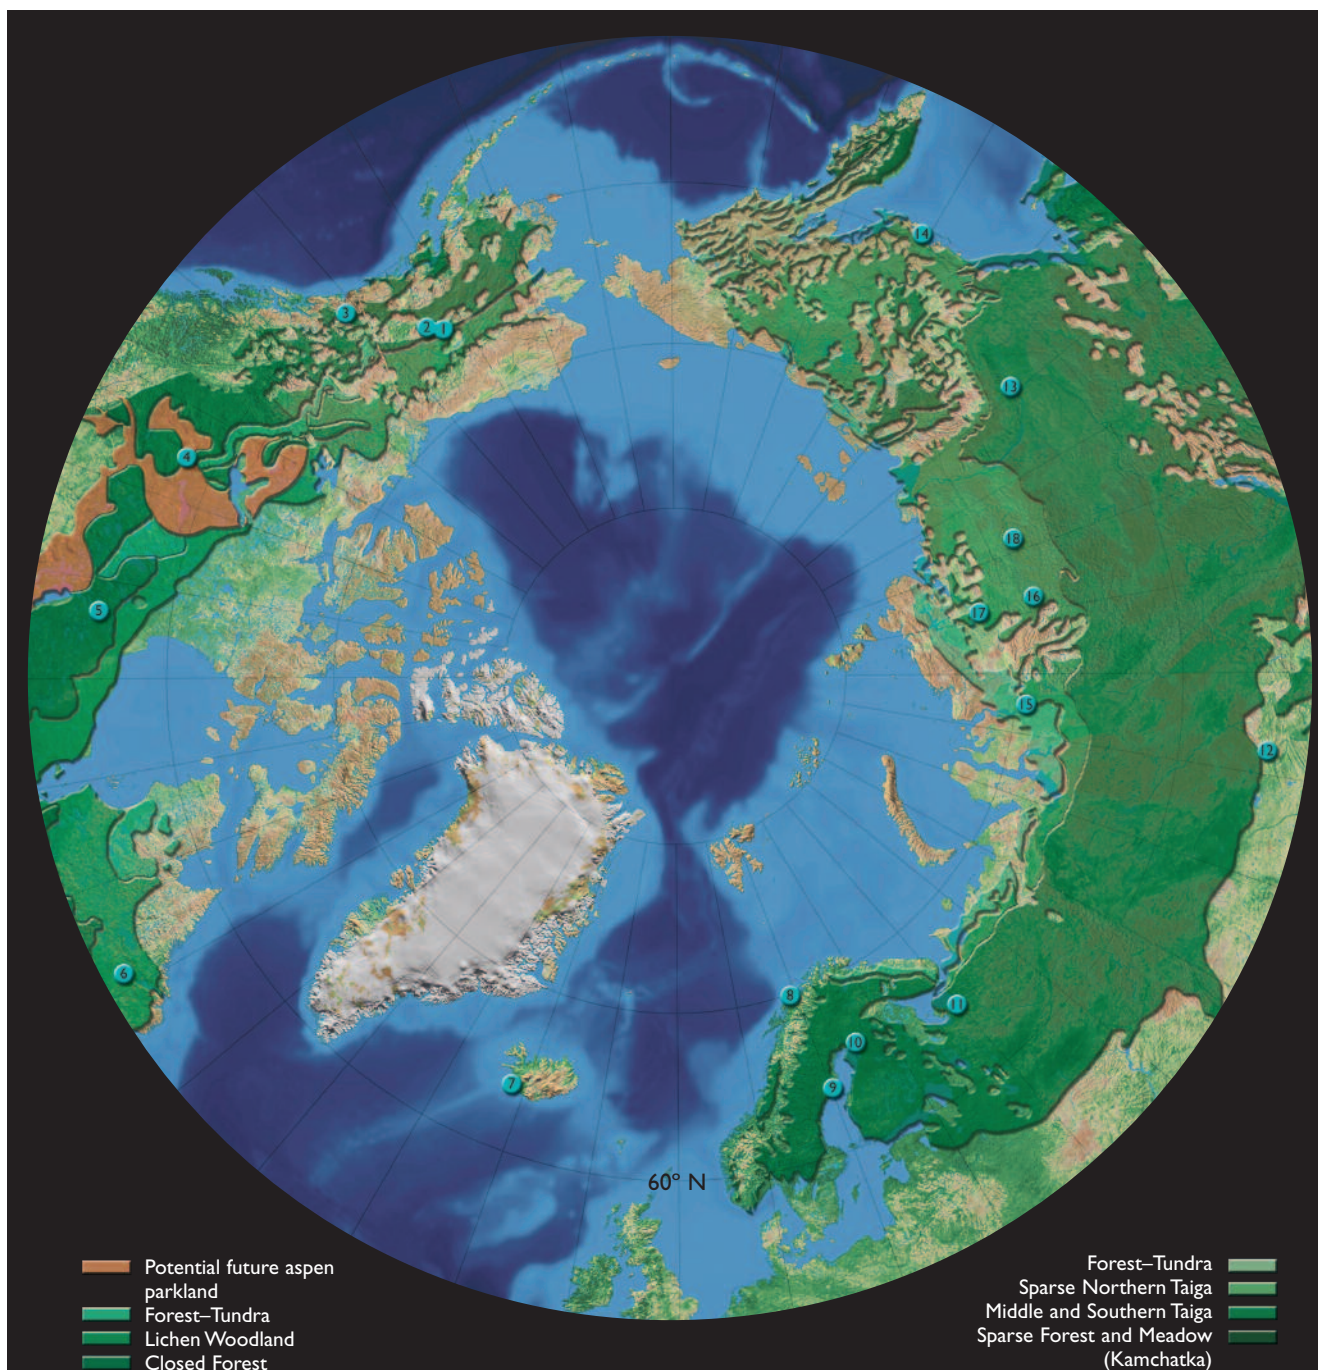
Precipitation is abundant in the boreal zone of most of the Nordic countries, western Russia, and certain coastal and mountain regions of western North America. By contrast, in the topographically complex


Fig. 14.1. Present-day boreal forest distribution, using a simplified formation system representing a gradient of decreasing productivity and species diversity from south to north (compiled using data from Anon., 1983; Anuchin and Pisarenko, 1989; Elliott-Fisk, 1988; Kuchler, 1970; Kurnayev, no date; Oswald and Senyk, 1977; Rowe, 1972; Viereck and Little, 1972). The area depicted in orange represents a broad zone where the ratio of precipitation to evapotranspiration is nearly one: under a scenario of doubled atmospheric CO_2, this area is projected to become too dry to support closed-canopy boreal forest, shifting instead to aspen "parkland", a woodland formation (Hogg and Hurdle, 1995). Numbered locations are sites analyzed in this chapter (see section 14.4.1, Table 14.2).

landscapes of Alaska, northwestern Canada, and central and northeastern Siberia, precipitation sometimes limits forest growth so that natural grasslands are part of the landscape.

Precipitation in the boreal region of western North America is influenced by storms in the southern Bering Sea and North Pacific Ocean and reaches a distinct maximum in late summer. In other parts of the boreal forest region, precipitation is more evenly distributed throughout the year or exhibits a winter maximum. East-central Siberia experiences low winter snow depths because the strong Siberian High suppresses precipitation. The boreal landscapes of far eastern Siberia and western North America are mountainous, whereas the topography of most of central and western Siberia and eastern Canada is characterized by low, smooth hills and level terrain. The mountainous boreal regions are characterized by sharply varying local climates (Pojar, 1996) and aspect-controlled differences in forest types (Viereck et al., 1986). As a result, the forest–tundra boundary is much more irregular there than on the plains of the central portions of the continents (Fig. 14.1). All of this regional climatic variation must be taken into account as a fundamental backdrop when considering climate change and ecological response in boreal forests.

In Eurasia and North America, both the northern and the southern boundaries of the boreal zone are not aligned at the same latitude east to west. The Icelandic and Aleutian Lows deflect storm tracks and advect relatively mild air masses northward as they approach the western margins of Eurasia and North America, respectively. As a result the boreal forest belt is located considerably farther north in both the Nordic countries and western North America than in the center of the continents (Fig. 14.1). In contrast, cold polar air flowing southward follows a persistent path along the eastern portion of both continents, and consequently the boreal forest belt reaches its southernmost limits there. In the center of the Eurasian landmass, the latitudinal position of the boreal forest depends mainly on the degree of continentality of the climate. The most northerly forests in the world occur along the Lower Khatanga River in central Siberia (72° 32' N), where the climate is more continental than either western or eastern Siberia. The warmer summer temperature in northernmost central Siberia is the critical factor that allows trees to survive there despite extreme winter cold.

14.2.4. Climate variability

Essentially all of the boreal forest in Alaska is north of 60° N, and practically all the boreal forest of eastern Canada is south of 60° N (Fig. 14.1). The boreal forest region is particularly prone to climatic variability because minor variations in key features of the atmospheric circulation can either intensify the advection of warm air into this naturally cold region, or enhance the distribution of cold air southward through the region. There is some evidence that the climate system in the far

north operates in a way that positive (western continent) and negative (eastern continent) anomalies operate in synchrony with each other. It appears that the intensification of meridional air mass movement is especially effective in warming the western margin of the North American Arctic while cooling the eastern margin of the continent (Fig. 14.2), leading to east–west temperature anomalies in the arctic and boreal regions (see also section 2.6.2.1, e.g., Fig. 2.7, and section 6.7.2).

Periods of major climate change, including alternating glacial and interglacial conditions, have repeatedly and drastically affected the northern regions of the planet (section 2.7). During the late Pleistocene and several previous glaciations, the present-day boreal region was mostly covered with glacial ice and forest organisms were largely displaced south of the current limits of the region (Wright, 1983; Wright and Barnosky, 1984; section 2.7). The relatively small unglaciated portion of the present-day boreal region was almost entirely treeless and contained assemblages of species unlike any found today (Anderson and Brubaker, 1994).

Present-day boreal forest vegetation characteristically has a large ecological amplitude (i.e., the ability to survive across a wide range of environmental conditions). The paleoenvironmental record and modern instrumental measurements demonstrate major shifts in temperature regimes in this region even during the time that forest has been present (sections 2.7 and 14.6), and the presence of this large ecological amplitude in the trees indicates that this wide range of possible temperatures is a consistent enough feature of the environment that it has required an adaptive response. Rapid and large changes in weather over the short term send signals through boreal systems that initiate vital processes such as infrequent periodic tree reproduction (Juday et al., 2003). On the one hand, this high level of natural climate variability suggests that during periods of climate
Fig. 14.2. Opposing high-latitude temperature trends from tree-ring reconstructions of mean annual temperature with a strong signal from eastern and central North America (data adapted from D'Arrigo and Jacoby, 1992, 1993; Jacoby and D'Arrigo, 1989) versus warm-season (Apr–Aug) temperature in western North America (observed and reconstructed from tree rings; Barber et al., 2004). Anomalies are calculated from the 1671–1973 mean.

change, the effects are more likely to be detectable at an earlier time in the boreal region than in many other parts of the earth. On the other hand, a long and persistent history of climate variability in the region suggests that organisms in the boreal forests of today may be among those better adapted to climate change because they have been filtered by many climate fluctuations in the past.

Because ecosystems quite unlike those of today have existed in the region in the past (Anderson and Brubaker, 1994; Wright, 1983; Wright and Barnosky, 1984), major climate change in the future is likely to produce ecosystems unknown today. The emergence of novel ecosystems (from the human perspective) is partly the result of individualistic species responses to changes in the environment. Each species has its own environmental requirements, tolerances, and thresholds, so that some species that co-occur today may not in the future, or existing sets of species may be joined by additional species (sections 7.3 and 7.6). Because of this property of individualistic responses to change in the environment, conservation efforts must be informed by monitoring the status of key species on a continuing basis. Conservation measures, such as modified harvest limits or fire management, must account for rapidly changing environmental conditions or changes in species populations not anticipated in management planning assumptions or outside historical experience in order to meet a goal of sustainability (Chapter 11).

The simultaneous pattern of temperature and precipitation anomalies can have important ecological impacts in forests of the north. Wildfire in the boreal forest is the product of short- to medium-term warm and dry conditions, usually associated with high-pressure dominance during the long days of summer (Johnson, 1992). Alternating periods of warm and dry versus cool and moist summer climate in central Alaska regulate the growth and reproduction of white spruce (*Picea glauca*), ultimately providing a mechanism to synchronize the production of seed crops to periods immediately following major forest fires (Barber et al., 2000; Juday et al., 2003). If future climate change alters not just the mean of climate parameters, but also the pattern of alternating warm/dry and cool/moist conditions, the resulting climate pattern could interfere with the reproductive success of one of the most widely distributed and dominant North American conifers. This example indicates the potential for subtle influences to be major factors in climate change effects.

14.2.5. Unique influences on climate

The Boreal Ecosystem–Atmosphere Study (BOREAS) was a large-scale, international interdisciplinary experiment in the northern boreal forests of Canada that began in 1993. Its goal was to understand how boreal forests interact with the atmosphere, how much CO_2 they were capable of storing, and how climate change will affect them.

Albedo measurements from BOREAS are among the lowest ever measured over vegetated regions, and indicate that the boreal forest (especially forest dominated by black spruce – *Picea mariana*) absorbs nearly 91% of incident solar radiation (Hall et al., 1996). In terms of water and energy balance, BOREAS found that the boreal ecosystem often behaves like an arid landscape, particularly early in the growing season. Even though the moss layer is moist for most of the summer, nutrient-poor soils and limiting climatic conditions result in low photosynthetic rates, leading to low evapotranspiration. As a result, relatively little of the available moisture is transferred to the atmosphere. Much of the precipitation penetrates through the moss layer into the soils, which are permeable, then encounters the underlying semi-impermeable layer and runs off. Most of the incoming solar radiation is intercepted by the vegetation canopy, which exerts strong control over transpiration water losses, rather than by the moist underlying moss/soil surface. As a result, much of the available surface energy is dissipated as sensible heat.

The BOREAS experiment also found that coniferous vegetation in particular follows a very conservative water-use strategy. Stomatal closure drastically reduces transpiration when the foliage is exposed to dry air, even if soil moisture is freely available. This feedback mechanism acts to keep the surface evapotranspiration rate at a steady and surprisingly low level (less than 2 mm/d over the season). The low evapotranspiration rates coupled with high available energy during the growing season can lead to high sensible heat fluxes and the development of deep (3000 m) planetary boundary layers, particularly during the spring and early summer. These planetary boundary layers are often characterized by intense mechanical and sensible heat-driven turbulence.

14.3. Land tenure and management in the boreal region

The influence of climate change on forest values and forest users depends on the amount and initial condition of the forest resource and the uses or intangible values of the forest for people, cultures, and economies. This section reviews forest extent, the overall allocation of forest land to different uses, the main patterns of forest use, the management systems, and the values generated by the boreal forest. Where these characteristics can be singled out by political jurisdiction or other means, the discussion is focused on the northern boreal forest. This discussion forms the basis for considering climate change impacts.

14.3.1. Russia

Russia contains the largest forested area of any nation, amounting to an estimated 763.5 million ha (FAO, 1999). The boreal forest of Russia can be thought of as three roughly parallel belts of southern and middle taiga, sparse northern taiga, and in the farthest north a forest–tundra region extending to the completely treeless tun-

Fig. 14.3. (a) Russian forest species cover types, with the region of the Central Siberia transect (Krasnoyarsk Kray region) outlined, and (b) vegetation zones and forests of northern central Asia (E.A. Vaganov, V.N. Sukachev Forest Institute, Krasnoyarsk, pers. comm., 2003).

dra (Fig. 14.1). Dominant components of the Russian boreal forest change from spruce in the west (European Russia), to larch in the center and east, to pine at various locations (Fig. 14.3a). In Northern Eurasia, especially in central Siberia (Fig. 14.3b) and the Far East, as much as 70 to 75% of taiga forests appear to be close to a natural state. The remaining forests consist of fragments and other human-influenced forest, and areas dominated by marsh–bog complexes.

The central and especially the southern taiga zones have a long history of quite intensive land use. Although large untouched areas are rare or absent even in northern European Russia, a much greater proportion of these forests exists in a natural state than in similar vegetation zones in the Nordic countries. The Karelian Isthmus region in the St. Petersburg Oblast is a good example. The forests of the Green Belt along the Finnish–Russian (Karelian) border are one of the most important centers of boreal biodiversity in Europe (Silfverberg and Alhojärvi, 2004). Many species in the Red Data Book (endangered) lists for Sweden and Finland still exist in relatively healthy populations in northwest Russia. Disruption or decline in the ecological health of these remnant natural forests in Russia resulting from climate change is very likely to have severe implications for the survival of the listed species, at least within Europe.

Economically exploitable forests total about half of the forested areas under state forest management in Russia, and are generally located in the southern taiga. The northern boreal forest of Russia is generally too

distant from transportation infrastructure and consumption centers to repay the costs of timber removal. The Russian forest sector is a major employer, with a work force estimated at 1.8 million people in the mid- and late 1990s. However, during the 1990s, public-sector forest management organizations often did not have enough money to retain employees, fight forest fires, enforce logging regulations, or make periodic inventories. A slow recovery of public-sector capacity has begun in more recent years.

A 1993 reform, the Basic Forest Law, started a movement toward market transactions in this sector. The Basic Forest Law allows forest leasing and auctions of standing timber, and forest leasing is the main market mechanism currently in use. In the early 1990s, rapid and unsustainable cutting of old-growth and mature forests began. After 1996, changes in forest management policy and better information resulted in a slowing of the pace of timber cutting in old-growth forests. The new Forest Code of the Russian Federation was issued in 1997. The Russian forest management system uses the term "Forest Fund" to refer to all forest and related lands under governmental jurisdiction, which in practice is nearly all the forest. The dominant part of the Forest Fund was (and still is) under the management of the Russian Federal Forest Service (Rosleskhoz), which manages about 94% of the total forest area in Russia, with another 4% belonging to agricultural organizations, 1% to the Committee of Environmental Protection, and 1% to other state bodies.

For management purposes, Russian forests have been divided into three categories based on economic and ecological characteristics. The first category comprises forests with a protective function, for example, watershed forests (20% of forested land), which are available for partial tree removal, sanitary tree felling, and small (maximum 10 ha) clear cuts. The second category consists of forests in inhabited areas and forests with low productivity (5.5% of forest area). The vast majority of the forest (74.5%) is included in the third category, industrially exploitable forests, where clear-cutting (up to 50 ha) is the main management practice. In addition to managing nearly all Russian forests, Rosleskhoz is also responsible for about 20% of the logging, in the form of partial and sanitary logging. Climate change impacts that disturb forest cover in category one and two forest are very likely to impose extra costs on managers, local governments, and forest users to stabilize or recover forests. In category three forest, actual or potential forest product values are at risk from climate change. However, because of the economic inaccessibility of the majority of this forest in the northern taiga, direct losses are likely to be relatively small overall.

As of 2000, the Russian Federation had 99 state zapovedniks, or strict scientific nature reserves, totaling 31 million ha or 1.82% of Russia's territory (Ostergren and Shvarts, 2000). Zapovedniks generally meet category I criteria of the World Conservation Union classifica-

tion of protected areas (IUCN, 2000). During the 1990s, Russia established 35 national parks totaling 6.8 million ha (0.40% of Russia's territory). There are plans to establish additional zapovedniks and parks (Colwell et al., 1997). Practically all the national parks are located in Forest Fund areas and are managed by the state forestry authorities. These areas are managed for a range of scientific and biodiversity values, and the main concerns are climate changes that could reduce the chances for survival of the protected species or ecosystems.

The forests of Russia are an important component of the global carbon cycle because of the extensive area of forest land and the high storage of carbon in cold soils. In consideration of its extensive and significant forest resources, Russia has obtained substantial carbon emission credits as part of its participation in the Kyoto Protocol (Webster, 2002). Fulfilling the potential of Russian forests to offset carbon emissions will require sustaining, and to some degree rebuilding, a land management capability over a vast area with certain fundamental aspects: forest inventory and measurement, surveillance and detection of forest health problems, trained and deployable fire control and management forces, and various resource management specialists. Many of the benefits of increasing carbon sequestration in Russian forests can be obtained as a direct result of implementing policies that are widely agreed to be rational and beneficial (Shvidenko et al., 1997), including measures such as harvest levels in line with actual growth, effective fire control forces in regions of high-value timber, and adequate regeneration efforts.

14.3.2. Canada

The Canadian boreal forest represents nearly 6.4% of global forest area according to the United Nations Food and Agriculture Organization (FAO) definition of forest (Table 14.1). Forests play a large role in the Canadian environment, economy, culture, and history. Forest (tree-covered land with a full canopy) and woodland (tree-covered land with less than a complete forest canopy) cover nearly half (44%) of the Canadian landscape, totaling about 401.5 million ha, according to Canada's Forest Inventory 2001 (Natural Resources Canada, 2004). Canadian forest land totals about 309.8 million ha, according to the 2001 inventory, and about 294.7 million ha are not reserved and therefore potentially available for commercial forest activities, although much of the land has not been definitively allocated as to use. The large majority of Canadian forest is crown land held for the public, with 71% controlled by the provinces and 23% under federal control (Natural Resources Canada, 2003). A few percent of Canadian forest land is managed by territorial governments and the balance is in private hands. Of the 401.5 million ha of tree-covered land in Canada, 22.8 million (5.7%) are by law managed to remain in a natural state. On another 27.5 million ha (6.8%), timber harvesting is excluded by administrative policy (e.g., on unstable soils or as habitat buffers along important lakes or rivers). The most acces-

sible forest land, and therefore the most likely to experience forest management activities, covers 144.6 million ha, or 36.0% of the total tree-covered area.

In the Canadian land tenure system, provincial governments are responsible for managing most of the land within their boundaries held for the benefit of the public (crown land). Until recently, the federal government held and managed land north of 60º N (an area not organized into provinces). However, in this area, by progressive steps, ownership and decision-making responsibility are passing to indigenous peoples and territorial governments. Simultaneously, lands of major conservation interest are being established as new national parks and wildlife refuges managed by the federal government. The indigenous peoples of Canada, who meet their cultural, spiritual, and material needs from their forest homeland, have a unique perspective and set of goals in forest management. Canadian land and forest management has changed significantly and is likely to change further as aboriginal title, treaty rights, and governmental responsibility to protect these rights are all more specifically defined.

The large majority of Canadian forest is boreal, with species such as white spruce, black spruce, aspen (*Populus tremuloides*), and paper birch (*Betula papyrifera*) having essentially transcontinental distributions. The forests of Canada are naturally dynamic, with large-scale disturbances quite typical. Across all Canadian forest types, insect defoliation affected 18.6 million ha in 2002 (Natural Resources Canada, 2003). Section 14.10.2 details the role of disturbance in the boreal forest with respect to carbon, and section 14.8.1 describes the role of forest insect disturbances in the boreal forest.

In the late 1990s, more than 300 communities in Canada depended largely on jobs in the forestry sector. During that period, the wood and paper industries and associated organizations employed more than 830 000 people, and paid more than Can$ 11.8 billion in wages annually. In 2002, 361 400 people were directly employed in the forest industry (Natural Resources Canada, 2003). Historically, Canada has been one of the largest suppliers of wood and paper products in the world, with 1995 shipments of manufactured forest products valued at Can$ 71.4 billion. Forest products exports from Canada contributed Can$ 39.6 billion to its net balance of trade in 2003 – almost as much as energy, fishing, mining, and agriculture combined. Canadian forests also contribute to uses and support industries providing billions of dollars in sales, including recreation, tourism, natural foods, furs, Christmas trees, and maple syrup. Much of the rapidly increasing recreation activity is forest-based. The number of visitor-days to forested national parks was 29.7 million in 1994.

Timber is harvested from about one million ha in Canada annually, or 0.7% of the total accessible, managed forest land. Allocations of timber resources are based on long-term goals for land use and forest man-

agement established in forest plans, and regional analyses and estimates of wood supply. On public (crown) lands, tenure arrangements with forest companies or communities to harvest timber are usually issued through contracts or licenses. Recent changes to legislation and tenure arrangements include provisions to license the harvesting of other forest resources such as blueberries or mushrooms. All harvest activities must also complement or integrate management objectives for wildlife, water, subsurface resources, hydroelectric energy, and transportation. The northwestern Canadian boreal forests of northern Alberta and British Columbia and the southern Yukon and Northwest Territories are the last regions of Canada to experience large-scale forest products harvest, beginning primarily in the 1980s. The installation of wood products processing facilities stimulated the expanded harvest in the northwestern Canadian boreal forest, and under the leasing system, large areas that are currently primary forest are now committed to eventual harvest.

The new emphasis in Canadian forest management typically includes the identification of objectives for the conservation of forests as a source of economic wealth, of habitat for wildlife and fish, of gene pools for biological diversity, and of water and carbon. Climate change calls into question the ability to adequately forecast future forest condition and growth and thus conduct meaningful planning. However, Canadian forest land managers are considering how to deal with climate change effects with specifically adapted silvicultural techniques for maintaining forest health, managing declining stands, regenerating disturbed areas with desired genotypes and species, and assisting in species migration (Parker et al., 2000).

Because of the large share of productive forest resources under Canadian provincial jurisdiction, an important source of leadership in developing coordinated forest policy has been the Canadian Council of Forest Ministers (CCFM), made up of the principal forestry officials of the provinces. Faced with public concerns about the extent of timber harvesting, and in response to the 1992 National Forest Strategy and the United Nations Conference on Environment and Development (UNCED), the CCFM developed a framework of criteria and indicators to define and measure progress toward sustainable forest management, in consultation with the entire Canadian forest community. The framework reflects the values of Canadians and identifies the forest features and uses they want to sustain or enhance, including indicators of environmental, social, and economic health.

Canada and 11 other countries have collaborated in the development of criteria and indicators for the conservation and sustainable management of boreal and temperate forests outside Europe (known as the "Montreal Process"). Climate change adds major uncertainty to basic assumptions about future forest condition, growth, and uses that are critical in making decisions in the present. For example, current forest harvest levels developed to meet the test of sustainability must be based on

projections of future forest growth and mortality. A major climate shift would alter these factors in ways not fully understood but very likely to be disruptive. The challenge is to decide what forest activities should be allowed today based on an assumed future in which climate change outside the range experienced in previous planning horizons may be having an effect.

14.3.3. United States (Alaska)

Alaska is by far the largest state in the United States, occupying about 20% of the area covered by the remainder of the nation or an area greater than the Nordic countries combined. The two different types of forest found in Alaska are coastal rainforest in southeast and south-central Alaska and boreal forest in northern and Interior Alaska. The coastal forest in Alaska covers about five million ha, but the most productive areas of this forest type are south of the Arctic as defined in this chapter. However, much of south-central Alaska is either coastal forest or a boreal–coastal forest transition and is within the Arctic as defined here. The amount of land in the boreal region of Alaska that supports at least 10% forest cover is about 46 million ha, or 41% of the state. Statewide, about 6.4 million ha or 16.3% of total Alaska forest land is classified as "productive" forest, that is, land capable of an average growth rate of 1.4 m³/ha/yr (Labau and van Hees, 1990). Even less of the Alaska boreal forest (12% or 5.5 million ha) is considered productive commercial timberland (Labau and van Hees, 1990).

Of the 114 million ha that make up Alaska, the federal government owned over 95% until Alaska became a state in 1959. The state government was granted the right to eventual ownership of 32 million ha (28% of Alaska) as a condition of statehood. To date the state of Alaska has received 27.4 million ha (85%) of its entitlement. Under terms of the Alaska Native Claims Settlement Act, Alaska Native corporations are entitled to receive 13.4 million ha (11.7% of Alaska), and most of that land has been conveyed. Individuals own only about 0.6 million ha (0.5% of Alaska). The private individual ownership category is expected to slowly increase as a result of government land sales and transfers. The federal government retains nearly 68 million ha in Alaska (60% of the state), including about 20.6 million ha in national parks and 31.1 million ha in national wildlife refuges.

National parks and wildlife refuges generally preclude resource development, but there are a few exceptions. In some circumstances, petroleum development can take place in wildlife refuges, and rural residents with a history of local use may obtain resources such as house logs, fuel wood, and poles for fish traps from national parks. Taking all federal land designations together, and including other protected land such as state parks, Alaska has probably the highest percentage (about 40%) of its area devoted to strict protection of natural habitats in the world. At least 25% of the productive boreal

timberland in Alaska is reserved by law from forest harvest, and a similar amount is estimated to be reserved by administrative policy (Labau and van Hees, 1990). Climate change effects on this strictly preserved land base are likely to involve primarily the temporary reduction or increase in the populations of certain species resulting from land-cover change. The intactness and extent of these ecosystems enhance the prospect of species survival, even following large-scale climate change. The prescription offered by conservation biologists that best equips species to withstand major movement of optimum climate zones is to maintain large-scale, topographically diverse landscapes with naturally functioning ecosystems (Markham and Malcom, 1996). Such a strategy preserves complete gene pools and specially adapted ecotypes, and provides maximum opportunity for natural migration and disturbance recovery. The current boreal forest is largely the result of such adjustment by the biota to the many cycles of glacial and interglacial climate changes during the Pleistocene. The current land allocation situation matches the conservation biology prescription for climate change resilience better in Alaska than in almost any other major forest region of the world.

The Alaskan boreal forest is currently used for a variety of economic, subsistence, recreational, scientific, and other purposes. Local-scale logging has been a traditional use for much of the 20th century. The boreal region has only small-scale wood products facilities: mainly small sawmills and facilities to manufacture specialty products such as house logs and birchwood items. Employment in forest products manufacturing industries, mostly in the coastal region, peaked in 1990 at just under 4000 people, constituting 1.4% of total Alaska employment in that year (Goldsmith and Hull, 1994), but was only about 600 in 2002 (Gilbertson, 2002). In the 1990s, the two major wood products manufacturing facilities (pulp mills) in the state, which were supplied by long-term (50-year) contracts, permanently stopped operations. Much of the current economic activity associated with the Alaska boreal forest is generated by the basic activities of exercising the rights and responsibilities of ownership. These activities include forest inventory, monitoring conditions and trends, wildland fire management, access administration, and permits for use. Those administrative activities will occur under any scenario for the future, although they might need to be intensified under certain conditions that could be caused by climate change.

In Alaska, there are so few roads that timber removal generally must meet the costs of building or extending surface transportation routes. Much of the productive forest is distributed in scattered small stands across large landscapes. As a result, productive timberland is, with a few exceptions, not economically accessible. If low-cost forms of access (e.g., winter roads on frozen ground) can be used, the area of forest with positive stumpage value increases. Climate change will decrease the amount of time when winter access is safe on ice bridges

and frozen winter roads (section 16.3.6, Fig. 16.21). Even a small amount of additional warming would initiate permafrost thawing across a sizeable portion of the interior boreal region (sections 6.6.1.3 and 16.2.2.3), severely disrupting the ground surface and causing widespread death of existing forest cover. Over the long term, however, sustained temperature increases are likely to expand the productive forest area significantly as long as available moisture does not become limiting (Juday et al., 1998).

The contributions of Alaska forests in providing subsistence food, fuel, building materials, and indirect ecosystem services, generally not measured by dollar flows, are very important in Alaska and probably exceed values from commercial timber operations in most of its boreal region. Alaska forests contribute ecosystem services especially important to the cash economy by providing commercial fisheries, sport hunting and fishing, and values of non-consumptive uses of the forest involving tourism, recreation, and enhancement of the quality of life. Scientific research is one of the most important current uses of the Alaska boreal forest, with climate change effects and carbon-cycle investigations major topics of continuing interest.

Over one million nonresident tourists visit Alaska annually, and the number of tourist visits has increased steadily over the last few decades (Northern Economics Inc., 2004). Forests create specific scenic resources for major segments of the tourism industry, including cruise ships and state ferry routes in Prince William Sound, and near the rights-of-way of the Alaska state highway system and the Alaska railroad. Beginning in the 1990s, large-scale insect-caused tree death and injury related to temperature increases was observed along several of the most popular and heavily traveled tourist routes. Recreation continues in those areas, but the quality of the experience for some visitors has been reduced.

If the assumption is made that demand and prices will rise and the public will allow expanded timber cutting under certain circumstances, the size and economic value of the Alaska forest products sector are likely to increase, and thus the risk of harm to this sector from climate change is likely to be greater. If the assumption is made that access will continue to be expensive (prohibitive), that manufacturing cost disadvantages in Alaska will persist, and that public attitudes about expanded timber cutting on the public lands are negative, the size and economic value of the Alaska forest products sector are likely to remain at current (historically depressed) levels or even decline further, limiting the magnitude of exposure to risk from climate change (Berman et al., 1999).

Much of recent Alaska forest management has been described as "opportunistic" (i.e., taking advantage of other events or projects to build programs and capabilities). Nevertheless, as inventory data accumulated, publicly built access systems expanded, and new scientific

insights and data handling tools became available in Alaska, professional forest managers anticipated they would be able to set and accomplish goals more systematically. However, the increased uncertainty associated with climate change that has already been experienced in Alaska makes long-term forest planning and management considerably more difficult. It is already unclear whether there is a reasonable probability that the cost of planting or regenerating certain stands in certain regions can be recovered in future forest harvests because of higher risk from climate-triggered insect outbreaks (section 14.8.2) among other climate change effects (drying lakes, shrinking glaciers, and large burned areas) already obvious on the landscape.

14.3.4. Fennoscandia

Finland, Sweden, and Norway have certain features in common. These nations extend from at least 60º N (or further south) to north of the Arctic Circle. Across that distance, these nations encompass north-temperate deciduous or transition forest and an entire gradient of the boreal forest to treeline and tundra in the north. Despite its northerly location, the climate of the region is the warmest of equivalent latitudes in the circumpolar world, due to the strong influence of the Atlantic Gulf Stream. Annual precipitation varies from 1500 mm or greater in western Norway, which receives the strongest Gulf Stream influence, to 300 mm in the northeastern portions of Finland. The growing season lasts 240 days in the south and 100 days in the north. Mean temperatures range from 14 to 17 ºC in July to between -14 and 1 ºC in January and February. The combination of relatively mild temperatures and a deep, dependable snowpack that insulates the ground even in the coldest northern areas means that permafrost is practically absent in forest regions.

Most of Sweden and Finland is characterized by relatively even topography and is less than 300 m above sea level. In the west, mainly in Norway, the Scandinavian mountain range reaches elevations of 1000 to 2000 m above sea level. These mountain peaks are not forest-covered. The treeline varies from 700 m above sea level in the southern part of the mountains to 400 m in the northern part.

In northern areas of Fennoscandia (and the adjacent Kola region of Russia), the Saami (Lapp) people pursue reindeer husbandry in forest lands on the basis of ancient rights. The Saami are legally entitled to use lands that belong to others in order to feed and protect their reindeer herds. Saami earn their living from reindeer breeding, and reindeer move through different areas throughout the year. The forest owners affected by the herds are under a mandate to cooperate with Saami communities to ensure that reindeer can obtain their life-cycle requirements. However, because these rights are exercised across four national jurisdictions, legal systems, and boundary controls, traditional flexibility is hindered (section 12.2.5.2). This jurisdictional complexity works

against adaptability of the herding system that would be desirable in response to climate change.

Due to the generally low buffering capacity of forest soils in the Fennoscandian region, a high level of air pollution, mainly originating abroad, has resulted in widespread soil acidification. Leaching of mineral nutrients has reduced soil-buffering levels by as much as half in recent decades. High levels of acid deposition (both sulfur oxides and nitrogen oxides) represent future risks to the growth and health of forest ecosystems. Overall, however, the measured rates of growth of managed and tended stands have increased considerably, which might be due at least partially to the nitrogen input.

14.3.4.1. Finland

Finland is the most heavily forested country in Europe, with 16 times more forest per capita than the European average. Forests as defined by the FAO cover 23 million ha or 74.2% of the land area. Finnish forests have been intensively harvested over the last few decades. Despite an active harvest program and the reduction of national territory after the Second World War (territory Finland ceded to the Soviet Union contained over 12% of its forest area and about 20% of the best saw-timber stands), Finnish reserves of wood volume are now greater than during the 20th century, and continue to increase. Today the annual aggregate wood growth in Finland is about 75 million cubic meters, while around 60 million cubic meters or less are harvested or die of natural causes. Of the total logged area, regeneration felling accounts for roughly one-third and thinning two-thirds.

In the boreal region, the most common trees are Scots pine (*Pinus sylvestris*), Norway spruce (*Picea abies*), silver birch (*Betula pendula*), and downy birch (*B. pubescens*). Usually two or three tree species dominate a given stand. Pure pine stands occur in rocky terrain, on top of arid eskers, and in pine swamps. Natural spruce stands occur on richer soil. Birch is commonly found as an admixture, but can occasionally form pure stands. About half of the forest area consists of mixed stands. Various kinds of peatlands are also an important part of the Finnish landscape. Originally, peatlands covered about one-third of Finland. Many peat areas have been drained for farming, forestry, and peat extraction purposes. Bog drainage reached a peak in the 1970s, when nearly 1% of the total land area of the country was being drained each year. About half of the original peatland area has been preserved in its virgin state.

Nearly all of the Finnish forest is intensively managed. In the 20th century, foresters favored conifers, especially pine, at the expense of other species. As the oldest generations of trees have been felled, the average tree age in the forest has become younger. Forest stand treatments and forest roads have fragmented large contiguous wilderness areas, and forest fires are largely prevented. Managed commercial forests of this kind now cover more than 90% of the productive forest land in Finland.

About 40% of all endangered species in Finland are dependent on older age classes of natural forest (Parviainen, 1994). Any climate change effects (intensified physiological stress, fire) that disproportionately affect the remnant of older forest are virtually certain to have large negative impacts on the survival of the rare elements of biodiversity.

With the implementation of new forest management and protected area programs, the contribution of forest harvest and management to species endangerment will diminish. For the moment, however, forestry is still a greater threat to the preservation of species than any other human activity (Essen et al., 1992). One reason for this is that about half of the plant, animal, and fungus species found in the country live in forests. Of the various factors attributable to forestry that reduce biodiversity, the most important is the rarity of larger, old trees – both live and dead (Essen et al., 1992). Specialist organisms such as arboreal lichens, wood-rotting fungi, and mosses and invertebrates have declined with the decrease in large old trees, snags, and logs.

Finland has 35 national parks that cover 8150 km^2. Together with other nature reserves, the total protected area amounts to approximately 29 000 km^2 or about 9% of the total land area of Finland. The Finnish government adopted a special protection program for old-growth forests in 1996 and for broadleaf woodland in the late 1980s. There are ten programs designed to protect various types of natural features and areas. The goal is to extend protection to over 10% of the national territory. As of March 2003, about 3.57 million ha of land to be protected had been identified. About 2.7 million ha had been included in the programs by the beginning of 1999. Protecting habitats either totally or partially from human activities is the main strategy to recover endangered species and encourage biodiversity. In the case of forests, this mainly means protecting the remaining old-growth stands of both conifer and broadleaf forest growing on rich soil as public reserves, as these habitats have been declining most rapidly. There are elaborate arrangements for consultation with landowners during the planning stages of protection programs. This process of consultation was followed when the areas for inclusion in the Finnish Natura 2000 scheme were being designated. The largest category of protected areas is wilderness in Lapland. Wilderness areas, established by the Finnish Parliament, cover about 15 000 km^2 of forest, treeline, and tundra habitats. Although strictly limited, some forest cutting is permitted in some parts of these wilderness areas.

Most of the highly productive forests in Finland, especially those in the southern and central parts of the country, are privately owned. Nearly 60% of the Finnish forest is privately owned and one in five people belongs to a forest-owning family, including a broad spectrum of the population. The average size of a private forest holding is 30 ha. Most of the forest in

Lapland is publicly owned, and as a result, the northern forests have been managed more uniformly and on a larger scale than those elsewhere.

Until the mid- to late 1990s, one-third of Finnish export earnings came from forests, and the forest products industry as a whole was second only to metal products as an export sector. The economic activity (turnover) of the forest sector was roughly Eur$ 23.5 billion: management activities contributed Eur$ 1.7 billion, the forest industry Eur$ 17 billion, and machines and other equipment EurR$ 5 billion. The Finnish share of the total value of global export trade in forest products was about 7.6%. Forest management and the forest industry employed about 100 000 people while the rest of the sector employed about 50 000 people. About 100 000 timber sales deals are made every year between forest owners and forest industry companies.

An environmental program for forestry was adopted in 1994 based on forest-related principles approved at UNCED in 1992 and the 1993 general principles for sustainable forestry adopted by European forest ministers in Helsinki. The goal of Finnish forestry has become ensuring a sustainable economic return as well as preserving biodiversity and facilitating multiple use of the forests. Management practices that strongly alter the environment, such as bog drainage, deep plowing of forest soil, and use of herbicides to kill undergrowth, have been almost totally abandoned. Habitats important to biodiversity preservation have been excluded from timber operations, and both living and dead trees are now routinely left in cutting areas to support biodiversity. Natural regeneration of trees has increased in importance relative to planting nursery-grown seedlings and more attention is paid to preserving forest landscapes.

The Government of Finland adopted a National Forest Program (NFP) in March 1999. The goals of the NFP are to increase the industry's annual consumption of domestic wood by 5 to 10 million cubic meters by 2010, double the wood processing industry's export value, and increase the annual use of wood for energy to 5 million cubic meters. The Finnish government, in collaboration with the forest industry, will also ensure competitive conditions for the forest industry (e.g., supplying energy at a competitive price) and launch the technology and development programs needed for promoting the wood processing industry and wood-based energy production. In addition to wood product utilization, the NFP recognizes and promotes other forest uses, including hunting, reindeer husbandry, wild mushroom and berry picking, scenic and cultural values, recreation, and tourism.

The forest sector in Finland also makes a unique contribution toward the goal of zero net emissions of CO_2. At present, about 20% of the total energy production in Finland is based on wood, which is substantial compared to the global average. The forest industry produces about 80% of the wood energy by burning black liquor, a by-product of pulp mills, and sawdust and chips from the wood processing industry. Pulp mills are completely self-sustaining in terms of energy and are even able to supply other plants with energy. Households and small heating plants produce about 20% of the wood energy. They use primarily small dimension wood from thinning, chips made out of logging waste, and building waste.

14.3.4.2. Sweden

Sweden is a heavily forested nation. Closed forest and forest plantations cover slightly more than 60% of the nation or about 27.1 million ha. Forested shrubland, which is especially common in the transition between closed forest and tundra, represents another 3 million ha or 6.6% of Sweden. Inland waters make up almost 10% of the country, and the non-forest land base is about 23% (FAOSTAT, 2000). Sweden has 25 national parks that together cover more than 0.6 million ha, or 1.5% of the area of the country. Sweden also has 1563 nature reserves covering 2.6 million ha, or around 5.5% of the area of the country. There are also other nature reserves and protected areas that are increasingly provided by private forest owners, including individuals and large forest companies.

One striking feature in Sweden compared to other timber-producing countries is that the national government owns only 5% of the productive forest lands. In 1993, most government-owned timberland was transferred to a forest product corporation – AssiDomän – of which the national government owns 51% of the shares and the remaining 49% are traded on the stock exchange. Private individuals (families), owning approximately half of Swedish forests, are the largest single category of forest owners. Forest companies own approximately 3% and other owners account for 12%. Forest industry land holdings are concentrated in central Sweden and some portions of Norrland (the northern three-fifths of Sweden), where the industry also operates many large, modern production facilities. Swedish forest companies have globalized their operations and established themselves firmly in the European countries and on other continents. At present, some 8 million ha of forest land have been certified in Sweden. Certification is a process of formal evaluation and recognition by third-party evaluators that forest products have been produced using sustainable management practices, and can be advertised to consumers as such. Forest companies account for most of the certified forest land.

Sweden has the highest population (8.8 million) of the Nordic countries, but is still largely a sparsely populated country, especially in the north. Despite the relatively low population density, Swedish forests show the effects of many centuries of human use. Only in the northern interior are the forests less affected by humans. Today much of the northern Swedish forest is protected, either as nature reserves or by other means.

The average size of a private forest is about 50 ha. Until the Second World War, most private forest owners were

farmers who lived on their property and were engaged in crop cultivation as well as harvesting wood products. Since then, the area of forest land devoted to this type of combined agriculture and forestry enterprise has dropped from more than 9 million to less than 4 million ha. Today many individual forest owners do not live on their forest land, but often in communities close to it or in more distant cities and towns. The bulk of forestry work on their properties is now performed by employees of forest owners associations or by other contractors.

Early in the 19th century, Sweden began the process of industrialization by rapidly expanding its sawmill industry. The major Norrland rivers were suitable for floating timber to the Baltic Sea, thereby opening up previously untouched inland forests to large-scale logging. The sawmill companies, which purchased very large tracts of land from farmers until 1905, soon gained a strong position in European timber export markets. Northern Sweden was very sparsely populated until the beginning of the 19th century. At that time, an accelerating agrarian colonization took place, and later in the century, large-scale exploitation of the virgin forest began. The first forest resources to be exploited were those close to the Bothnian coast, and subsequent exploitation moved further inland. This exploitation affected almost all forest land in northern Sweden between 1850 and 1950.

The boreal forest landscape in Sweden has changed dramatically during the last 150 years. Owing to the vigorous pursuit of forest management goals over the last 100 years, widespread stands of commercially tended Scots pine of generally similar age and structure make up most of the northern Swedish landscape (Essen et al., 1992). Less than 3% of the forest area of Sweden supports trees older than 160 years, and less than 2% of the conifer volume is in trees with diameters greater than 45 cm (Essen, 1992). The volume of standing dead trees in Sweden has decreased by more than 90% in the last century and the number of large-diameter conifers (>30 cm diameter at breast height) has decreased by more than 80% (Linder and Ostland, 1992). Many old-growth specialist species, including arboreal lichens, mosses, insects, wood-rotting fungi, and cavity-nesting insectivorous birds, have become rare in boreal Sweden (Essen, 1992). All the taxonomic groups that are represented in the 1487 threatened forest species in Sweden include elements that are largely dependent on old forests or the habitat elements of old forests (Berg A. et al., 1994). Many of these species belong to functional groups, such as insect predators, that perform vital functions for the health and productivity of the forest system as a whole. As a result, the northern Swedish forest is particularly vulnerable to any climate change effects that would accelerate tree mortality in older stands.

About 20% of the energy consumption in the country originates from forest biomass, and there is presently a significant annual accumulation of carbon in standing biomass, equal to approximately 30% of Swedish fossil fuel emissions. The high level of air pollution originat-

ing outside the country and the accelerated leaching of mineral nutrients in Sweden has resulted in widespread soil acidification. Forest-damaging amounts of both sulfur dioxide and nitrogen oxides are being deposited. The accelerated leaching of mineral nutrients caused by acid deposition has reduced nutrient levels by half on some sites in recent decades, although nitrogen deposition increases supplies of a critical nutrient. Air pollution poses a serious threat to the health and growth of Swedish forest ecosystems. In general, researchers believe that multiple stresses may act synergistically, resulting in acceleration of change due to other stresses (Oppenheimer, 1989). Climate change, therefore, must be understood to be acting in this context in Sweden, as one among many factors.

The present-day timber stock is 50% larger than it was when detailed measurements began in the 1920s. However, for much of the early and mid-20th century, forests in Sweden were exploited in ways that today, with increased knowledge and insights, are understood to be detrimental to the environment. Clear-cutting was extensive, and little effort was made to protect biodiversity. Since the 1992 UNCED meeting, the concept of sustainability has broadened. This is reflected in the revised Swedish forestry policy that went into effect in 1994. The 1994 Forestry Law states: "The forest is a national resource which should be managed so that it provides a good return on a sustainable basis and ensures the preservation of biodiversity". These two goals have equal priority (Lamas and Fries, 1995). Underlying this policy is the conviction that there will continue to be a demand for renewable products in the future and that Swedish forests can remain an important source of natural raw material produced using principles based on ecological cycles. Swedish forest legislation protects key woodland habitats, forests located near high mountains, and wetland forests. Special regulations govern four million ha of low-productivity woodlands that are not included in the productive forest land, allowing only careful low-intensity utilization and ensuring that their basic character remains unchanged. Hydrologic and other possible changes resulting from climate change represent potential risks for some of these protected features.

Swedish forest policy also states that forests should be able to sustain hunting and the gathering of wild mushrooms and berries as well as active silviculture. The "right of common access" is traditional in Sweden. People are entitled to hike through the natural landscape and to pick mushrooms and berries regardless of who owns the land. This tradition broadens the pool of resources and users with specific concerns about potential climate change impacts beyond those of timber and a comparatively small number of forest-land owners. Hunting and fishing remain widespread and significant activities in Sweden, and are considered in forest management since they are connected to key management practices. Sports such as orienteering, cross-country skiing, and other popular outdoor activities that take place in the forests involve a relatively large proportion of

people in Sweden. Participants in these sports have a strong interest in the health of the forests and are an important forest and climate change constituency even though they do not remove products from the forest.

14.3.4.3. Norway

Forests and other wooded land cover about 37%, or 11.9 million ha, of the Norwegian mainland. Nearly 23%, or 7.2 million ha, is regarded as productive forest. The productive forest is distributed among 125 000 forest properties, and about 79% is owned by private individuals.

The total area of wilderness territory in Norway has been greatly reduced over the past 100 years. Wilderness territory is defined as areas more than 5 km from roads, railways, regulated watercourses, power lines, and vehicle tracks. Although the largest 20th-century reduction in wilderness occurred in the lowlands of southern Norway, where wilderness is now virtually eliminated, mountainous areas and northern Norway have experienced major wilderness reductions and fragmentation as well. Today, wilderness represents 12% of the total land area of Norway (not including Svalbard and Jan Mayen). Approximately 6.4% of mainland Norway has official protected area status. New protection plans, especially for additional national parks, are being developed, and about 15% of the land base will be within protected areas by the year 2010. Both public and private lands that lie within or adjacent to designated national parks are protected from construction, pollution, or any other encroachment.

Norwegian forests have been exploited intensively for the export of roundwood, sawn timber, and wood tar for hundreds of years. In addition, there is a long tradition of using the forests for domestic animal grazing and game hunting. For many years, the amount of wood removed from Norwegian forests has been less than the amount of growth. The biomass of standing trees has almost doubled since 1925, and the volume of standing forest increased by more than 95% from 1925 to 1994, to about 616 million cubic meters. In 1994, the net increase (increment or growth minus removal) in forest mass was 9.5 million cubic meters, or 1.5% of the total volume of standing forest. The 1994 volume of Norwegian forest consisted of 46% spruce, 33% pine, and 22% deciduous trees. The net volume increase was greatest for deciduous trees and pine. Because of their increase in total biomass, Norwegian forests have contributed to a net transfer of CO_2 from the atmosphere into storage during the 20th century. It is estimated that in 1994, the net amount of CO_2 assimilated by forest was 15 Tg, amounting to about 40% of Norway's annual anthropogenic emissions.

The increase in wood volume can be attributed to many factors. A sustained effort at intensive forest management has systematically removed older stands that have low rates of net growth, and increased the proportion of stands in the early and most rapid stages of growth. An extensive afforestation effort has established forests on sites such as formerly open wetlands that previously supported no (or only minor) forest cover. Natural forest vegetation has returned to uncultivated land that is no longer farmed, producing a gradual buildup of vegetation mass. Long-range transport of nitrogen in precipitation has had a fertilizing effect on Norwegian forests. Finally, the introduction of new species that grow faster than native species on some sites has also led to greater forest growth. It should also be noted that the particularly large increase reflected in the inventory data for the most recent years is probably due in part to new methods of calculation.

Today the forest is used first and foremost as a source of raw materials for sawmills and the pulp and paper industries. Government grants or subsidies for forest planting began as early as 1863 in Norway. In recent years, forest planting has been somewhat reduced to between 200 and 300 km^2 of forest planted or sown annually. Norwegian plantations are often spruce monocultures. The diversity and abundance of the fauna and flora in planted spruce forest is much lower than that in naturally regenerated forest.

Although the volume of forest has increased considerably since the beginning of the 20th century, the present-day forest has been transformed from its original condition. Clear-cutting, plantation establishment, introduction of alien species, ditching, and forest road construction are some of the intensive forest management measures that have been applied. Acidification and pollution have also affected forests. As in the other Nordic countries, management practices applied in order to produce increased tree biomass have caused a reduction in biological diversity. Much of the present forest growth is concentrated in large monocultures. Large stands of the same age class contribute to a reduction in the number of species of flora and fauna compared to what would occur in a more natural, mixed type of vegetation.

Forestry and the forest industry are important sectors of the Norwegian economy. Wood and forest products represent about 11% of Norwegian non-oil exports. This is slightly less than the export value of the Norwegian fishing industry, somewhat higher than both aluminum and natural gas export values, and twice the value of Norwegian high-technology exports. About 30 000 people receive their income from primary forestry and the forest industry. Most of the economic activity in the forestry sector takes place in rural districts and is particularly important in these areas that have fewer economic alternatives than urban zones. Norway began exporting large quantities of sawn lumber in the 16th century and continued this practice for several centuries. However, since the Second World War, most of the sawn lumber has been utilized nationally. Most homes in Norway are constructed of wood, with wooden interior fittings, and wood is an important part of the everyday life of Norwegians. In 1995, the

wood processing industry used 5.1 million cubic meters of wood and employed about 16 000 people.

Sawmills use about 50% of the Norwegian roundwood harvested. There are 225 sawmills in Norway operating on an industrial scale. Paper products have the highest export values of all the forest-based products. Paper and board products are currently produced by 36 different machines in Norway. Wood pulp and chemical pulp are produced by 17 production units. Every year, Norway exports about one million tonnes of newsprint. The pulp and paper industry employs 9000 people.

Until a century ago, wood was the dominant energy resource in Norway. Oil and hydropower are currently the major energy sources, and fuelwood use is only 7% of the volume used 100 years ago. However, the forest may play an increasing role as an energy supply. Shortages of electricity and CO_2 taxes on the use of oil have increased the interest in bio-energy. Today, the pulp and paper industry is by far the largest producer of bio-energy in Norway.

14.3.4.4. Iceland and Greenland

As a geologically young landform situated along the mid-Atlantic Ridge, isolated from both Europe and North America, Iceland has always supported ecosystems with a restricted set of species (only about 483 native and naturalized vascular species; Icelandic Institute of Natural History, 2001). Iceland is also the area of the Arctic with the most substantial human impact on ecosystems. At the time of Viking settlement in the year 874, vegetation was estimated to cover about 65% of Iceland, while vegetation covers only about 25% of the island today (Blöndal, 1993). This reduction in vegetative cover is most likely the result of intensive land and resource utilization by a farming and agrarian society over 11 centuries, although recent investigations also suggest that specific years of low temperature and low precipitation possibly initiated devegetated patches under a traditional winter grazing system that was abandoned in the early 20th century (Hellden and Olafsdottir, 1999). Estimates vary as to the percentage of the island originally covered with forest and woody vegetation at settlement, but a range of 25 to 30% is plausible (Blöndal, 1993). The native forest of Iceland was principally comprised of downy birch and a few tall willow species with a relatively large proportion of the woody stems in a dwarfed and somewhat contorted growth form. Rowan (*Sorbus aucuparia*) and European aspen (*Populus tremula*) occasionally occur among the birches. Tea-leaved willow (*Salix phylicifolia*), hairy willow (*Salix lanata*), and creeping juniper (*Juniperus communis*) are common shrubs in birch woodlands. Ancient native birch woodlands and scrub are key areas of terrestrial biodiversity in Iceland. The birch woodlands still retain most of their original biodiversity and are a key habitat for a number of threatened and endangered species, while the deforested land has suffered degradation and in some cases has been reduced to deserts.

When Norse farmers, traders, warriors (Vikings), and seafarers arrived in Iceland from western and/or northern Scandinavia, Ireland, and Britain in the 870s and 880s, the land was uninhabited and vegetated from the seashore to all but the glaciated mountains. At higher altitudes, the woodlands gave way to dwarf birch (*Betula nana*), willow, grasses, and moss. Birch woodlands separated by wetlands dominated the lowland vegetation. The lowlands were the only habitable land areas and were occupied in the first decade or two of settlement. Most of the first settlers were farmers that brought livestock to the island. Forests were cleared rapidly by burning and harvest for building materials and charcoal manufacture, generally within 50 years of the arrival of the settlers. Nearly all of the habitable woodlands were converted to pastures and only the mountainsides and highland margins retained forests, which survived to the early 19th century.

In southern and western Iceland, the land was cleared and barley was grown. Domestic livestock were sustained at numbers that caused landscape degradation, soil loss, and reduced long-term productivity of pastures. A pollen record from Iceland (Hallsdóttir, 1987) confirms the rapid decline of birch and the expansion of grasses between AD 870 and 900, a trend that continued to the present. As early as AD 1100, more than 90% of the original Icelandic forest was gone and by 1700, about 40% of the soils had been washed or blown away. Vast gravel-covered plains were created where there was once vegetated land.

The exploration of Greenland in 984 by Eric the Red gave the more adventurous Icelanders new farm sites and freedom from limits on establishing themselves in an occupied landscape. The small areas of woodlands in Greenland, dominated by birch and willow in the south and alder (*Alnus* spp.) in the valleys of the Western Settlement, were highly valued. The Greenland Norse were also farmers, although they supplemented their diets with seal, birds, and reindeer/caribou. For several centuries the Norse remained committed to their farming way of life but gradually experienced various stresses (land degradation, trade and genetic isolation, social and economic challenges), many of which were aggravated by a cooling climate. The Norse settlements in Greenland and Iceland were established shortly after the beginning of a period of relatively warm and stable climate that persisted from the 8th through the 12th centuries (Ogilvie and McGovern, 2000). With the gradual degradation of the landscape that reduced its capacity to support livestock and crops, and during a severe cooling period between 1343 and 1362, the Norse presence in the Western Settlement of Greenland ended and the Norse population disappeared. The mid-14th century cold interval in Greenland was probably the period of the lowest temperature in the last 700 years, and the effect of this climate change on the Norse community is highly likely to have been an important factor in its terminal decline (Ogilvie and McGovern, 2000). Simultaneously, arctic-adapted

Thule people arrived for the first time as the culmination of their historic expansion eastward and may have played a role in displacing the indigenous Norse people who first inhabited the area.

Until quite recently, efforts to conserve and increase the area covered by native woodlands in Iceland were hindered because the majority of woodlands were subject to grazing, mainly by sheep: the total area covered by birch woodlands does not appear to have changed significantly in recent decades. However, the establishment of the Icelandic Soil Conservation Service in 1907 was instrumental in fencing off and halting the most severe erosion processes in lowland areas of southern and northeastern Iceland. This is a unique context in which to consider climate change effects in the Arctic – humans have damaged soils and eliminated so much of the native forest ecosystems in Iceland that climate change represents an opportunity for forest recovery and expansion.

Starting in 1907 but especially since the mid-20th century, efforts were made to establish forest plantations in Iceland. Plantations now total at least 20 000 ha (Gunnarsson K., 1999). Until the 1980s, the lands most suitable (from the standpoint of soils and climate) for re-establishing native birch forests remained committed to farming and winter fodder production for sheep and horses. However, since Iceland joined the European Economic Area and the World Trade Organization, Icelandic agriculture has been integrated into a trading and market zone in which many of its products fall under production quotas or price disadvantages. Farms are going out of traditional agricultural production, while other forms of land use, such as afforestation and horse farming, are increasing.

About 130 tree species from most of the cold regions of the world have been evaluated for their growth and survival characteristics (Blöndal, 1993). Different types of forest are being established for particular purposes. Native birch forest is often favored in recreation areas near urban centers and private land surrounding weekend recreation cottages in the country. Usually, land that is being converted to native birch forest must be fenced to exclude sheep. Protection forests are designed to prevent erosion of exposed soil, which is still quite common. Species commonly used in protection forests include downy birch, Sukachev larch (*Larix sukaczewii*), Siberian larch (*L. sibirica*), lodgepole pine (*Pinus contorta*), willows, and alder. A program to afforest denuded or severely eroded land has resulted in the planting of about one million trees in 70 areas subject to soil erosion. Production forests are designed to produce timber, fuelwood, and Christmas trees. Planted species include Sitka spruce (*Picea sitchensis*), Sukachev and Siberian larch, lodgepole pine, and black cottonwood (*Populus trichocarpa*). State-supported afforestation projects were initiated in recent years in all parts of Iceland, starting in eastern Iceland in 1991. The aims of the projects are to create jobs in the rural areas

(e.g., in nurseries) and to support jobs on those farmsteads taking part in the project. Farmers who participate in the project can receive a state grant of 97% of the total cost of afforestation on their farmlands (Gunnarsson K., 1999).

Until the 1970s, most plantations were established within the existing birch woodland, but that is no longer the case. Approximately 2000 ha of mainly non-native tree species have been planted annually in Iceland since 2003. In the late 1980s, forest and woodland vegetation covered only about 1.33% of Iceland, amounting to about 117 000 ha of native birch woodland and 15 000 to 20 000 ha of plantations. More than 80% of the woodland remaining in Iceland was less than 5 m in height in the 1980s, and 14.2% of the birch woods have trees taller than 5 m (Sigurdsson and Snorrason, 2000). In 2001, Iceland had 3 national parks totaling 189 000 ha and 35 nature reserves totaling 225 000 ha (Icelandic Institute of Natural History, 2001).

The main challenge to successful introduction of tree species to Iceland has been finding varieties that can survive and reproduce in an environment of strong, steady winds and growing seasons at the cool margin of tree tolerance. Warmer climate conditions generally increase the planting success and particularly the growth of trees in Iceland. The restructuring of the rural economy to include less production agriculture and more ecotourism, recreation, and amenity-based uses is supporting the trend toward the conversion of the Icelandic landscape from a treeless farming region into one with expanded forest area. The government program to sequester CO_2 has increased afforestation efforts. Most of the tree planting for carbon sequestration is contracted to farmers. A national goal is to expand forest cover on 1% of the national area per decade until forests cover about 5% of Iceland, which would represent the greatest forest extent in a millennium. In 1995, the estimated annual carbon sequestration by Icelandic plantation forests was 65 Gg CO_2, or about 2.9% of the annual national emissions at the time. By 1999, the annual sequestration totaled 127 Gg, representing 4.7% of annual emissions (Sigurdsson and Snorrason, 2000).

Approximately 70% of forests and woodlands in Iceland are privately owned, with the remainder owned by the national government or local municipalities. The Iceland Forest Service, an agency under the Ministry of Agriculture, is primarily responsible for implementing and monitoring government forest policy. The Environment and Food Agency of Iceland, part of the Ministry for the Environment, plays a role in the conservation of protected native birch forests. The main forestry laws in Iceland include the Forestry Law (1955), the Farm Afforestation Law (1991), and the Southland Afforestation Law (1997). In response to a request by the Icelandic parliament, the Iceland Forest Service prepared a comprehensive afforestation plan for all of Iceland as a part of its sustainable devel-

opment strategy, resulting in the Regional Afforestation Law (1999). The Icelandic Soil Conservation Service, also under the Ministry of Agriculture, is responsible for implementing the Soil Conservation Law (1965), which also contains provisions for vegetation conservation and restoration.

14.4. Use and evaluation of the ACIA scenarios

14.4.1. Method of analysis

This chapter uses the projections from the five ACIA-designated models (section 4.2.7) primarily in the form of numerical output for key climate variables in specific grid cells across the area of analysis. Criteria for selecting the models and assumptions used in generating the scenarios are described in Chapter 4. For the purposes of this chapter, 14 sites were chosen that are broadly distributed across the northern part of the boreal region or are located somewhat south of the Arctic but currently experience climate conditions projected to occur in the Arctic and boreal region by the ACIA-designated models. Most of the locations were chosen because they have a medium- to long-term record of climate conditions. Many are major population, trade, or transportation centers within their respective regions, and the sites are representative of most regions in the far north where agriculture and

[a]Analysis of growing degree-days only

forest management are currently (or potentially could be) practiced. The selected locations include areas in the eastern, central, and western portions of both Eurasia and North America (Table 14.2 and Fig. 14.1).

The primary variables obtained from the climate model output were mean monthly temperature, total monthly precipitation, and growing degree-days (GDDs). Mean monthly temperature is the mean of all mean daily temperatures for the month. Mean daily temperature is the mean of the high and low temperature on a given day. Mean monthly temperature integrates much of the short-term variability in weather and yet preserves a specific seasonal signal of warmth or coolness that has proven useful in many applications such as tree-ring studies. Total monthly precipitation reflects the amount and timing of moisture, and is widely used in forestry, agriculture, and hydrological applications. Growing degree-days are a measure of accumulated heat energy, calculated by taking the sum of daily mean temperatures above some defined threshold. For example, if the threshold value for accumulation is 5 °C, then a series of daily means of 2, 6, 7, and 5 °C would accumulate respectively 0, 1, 2, and 0 degrees for a total of 3 GDD.

Output climate variables from the ACIA-designated models were obtained generally for the period 1990 to 2099, which allowed an 8- to 10-year overlap with recorded data (typically 1990 or 1991 through 1998 or 1999). In some cases, recorded data from stations were truncated in 1989 or 1990, in which case model output from 1980 to 2099 was used in order to generate a 9- or 10-year overlap. For each station, the differences between monthly or annual values of the model output of temperature or precipitation representing the entire grid cell and the values measured at the specific recording station were calculated for the overlap period. From these differences, an overall mean difference was calculated and applied as a correction factor to the model output for all years beyond the overlap period. The variance was not adjusted, although some features of scenario versus recorded variance were examined (see section 14.4.4). The adjustment of general circulation model (GCM) output for use at a specific location is an active area of ongoing research (e.g., Hewitson, 2003).

14.4.2. Size and placement of grids

Grid cells in GCMs are large polygons that represent the surface of the earth. In the output from the ACIA-designated models, a specific climate variable is represented by a single value for an entire grid cell. Climate at a specific station location within the grid cell can be different from the value that expresses the entire grid cell for several reasons. It is important to understand what causes some of these differences in order to properly evaluate the scenario output and the ways it is used in this chapter.

The different GCMs use grid cells of different sizes and non-uniform placement. A grid cell that contains a given
station location may be represented as a polygon largely north of the station in one model but largely south of the station location in another model, and the temperature values generated by the two models will have a different relationship to the location of the climate station. The topography of the earth is another factor that can cause a difference between a climate station and a grid cell value. In one model, values for high- and low-elevation terrain may be integrated to calculate a single number for the climate parameter, whereas in another model the grid cell may be placed in a way that the surface of the earth is more uniformly high or low.

Mountain terrain often produces sharp gradients in precipitation. As a result, grid cells that include mountains and smaller valleys exhibit particularly large differences in precipitation compared to recording stations that are typically located in low-elevation valleys.

A small grid cell occupying an area along a mean frontal position in one model will show greater climate variability than a larger cell in the same model even if both contain the same recording station. In addition, different models produce different patterns of air-mass mixing, and as a result different patterns of mean frontal positions.
14.4.3. Range of scenarios

The ACIA-designated models project a range of annual and seasonal mean temperatures by the end of the model runs in 2099. The grid cell containing Ari Mas (on the Taymir Peninsula, Russia, and site of the mostly northerly treeline in the world; Jacoby et al., 2000) provides an example of these different temperature projections (Fig. 14.4). The Ari Mas grid-cell data was adjusted as described in section 14.4.1 using the mean annual temperature from four stations (Dudinka, Essej,

Khatanga, and Olenek), which averages about -11.5 ºC for the available 20th-century record. The long-term mean (regression line fit) for the CGCM2 output of mean annual temperature adjusted to the stations reaches about -7.2 ºC at the end of the scenario period, while the CSM_1.4 output increases to about -2.7 ºC by the end of the period (Fig. 14.4). The CGCM2 projects a climate in this grid cell at the end of the century that is within the range of forest–tundra transition conditions, whereas the CSM_1.4 projects mean annual temperatures typical of regions where today some of the more productive examples of the northern boreal forest occur.

It was sometimes possible in the analyses to calibrate the response function of a key outcome, such as tree growth, to climate. Often the different scenarios produced similar results, with differences mainly in short-term (interannual) variability. The graphic display of such results overlaps to such an extent that clear trends are difficult to see. As a result, when the outputs of a climate variable of interest were broadly similar among the five scenarios, the high- and low-end members were used to examine the range of consequences produced by the scenarios. Using the Ari Mas region again as an example, warm-season (May–September) temperatures projected by the ECHAM4/OPYC3 model increase by about 5.7 ºC and those projected by CSM_1.4 by about 3.0 ºC (Fig. 14.5). The warm-season mean is closely related to the mean radial growth of trees at this location, so the scenarios provide some basis for understanding what the effects of temperature increases at this location might be on tree growth and vigor (sustained rate of growth over time). Note the generally close relationship in Fig. 14.5 between the regional tree-ring growth signal, and the mean May through

Fig. 14.4. Observations and projections of mean annual temperature for Ari Mas, Taymir Peninsula, Russia. Observations represent the average of four climate stations (Dudinka, Essej, Khatanga, and Olenek) on the Taymir Peninsula; projections from the CSM_1.4 and CGCM2 models have been adjusted using the average mean annual temperatures from these four stations (see section 14.4.1).

Fig. 14.5. Historic relationship between growth of Siberian larch and warm-season (May–Sep) temperature, and projections of future warm-season temperature increases in the Taymir Peninsula, Russia. Observed temperatures are the average of four stations (Dudinka, Essej, Khatanga, and Olenek); model-projected temperatures are for the entire grid cell and have been adjusted (see section 14.4.1). Tree-ring widths are shown as de-trended and normalized index values (standard deviation from the long-term mean of each measured series; data from Jacoby et al., 2000).

May–Aug temperature (°C)

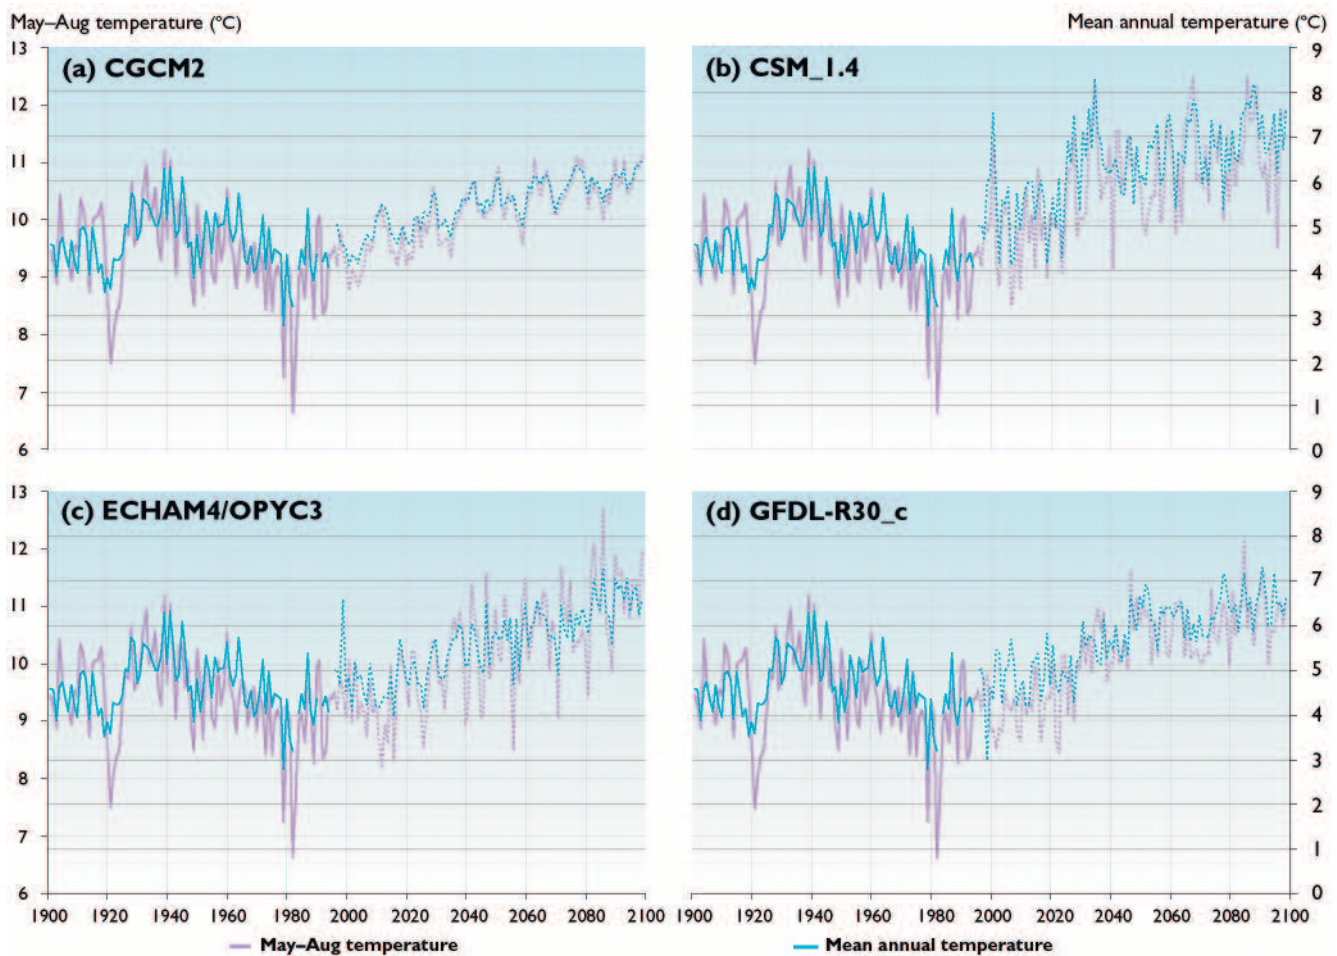
Mean annual temperature (°C)


Fig. 14.6. Relationship between summer (May–Aug) and mean annual temperature at Reykjavik, Iceland, for the period of the instrumental record and the ACIA scenario period.

September temperature. Siberian larch is heat-limited and displays a positive growth relationship with temperature. The ECHAM4/OPYC3 scenario for the 21st century projects temperatures that would approximately double the rate of growth and make this marginal site a productive forest. The CSM_1.4 scenario does not project the same degree of warming, but would eliminate periods of severe growth limitation. It should be remembered that the relationship of tree growth to climate may change under an altered climate.

Very few of the examined model outputs showed cooling or no change. The exception in the analysis is Reykjavik, Iceland. The CGCM2 and GFDL-R30_C scenarios for the grid cell that contains Reykjavik project mean annual and summer (May–August) temperatures that generally are not warmer than 20th-century observations, and temperatures at the end of the 21st century that are near the long-term means of the recorded data (Fig. 14.6a,d). Other model scenarios for the Reykjavik grid cell generally show a warming trend (Figs. 14.6b,c), but the magnitude is notably less than most of the other grid cells and stations examined. The four scenarios shown in Fig. 14.6 produce higher values of both summer and mean annual temperature than were recorded during the mid-20th century temperature peak, but in this highly maritime area none of the scenarios greatly exceed the mid-20th

century temperatures. Note the variability in the degree to which the different scenarios reproduce the historical relationship between the two variables depicted.

14.4.4. Variability and seasonality

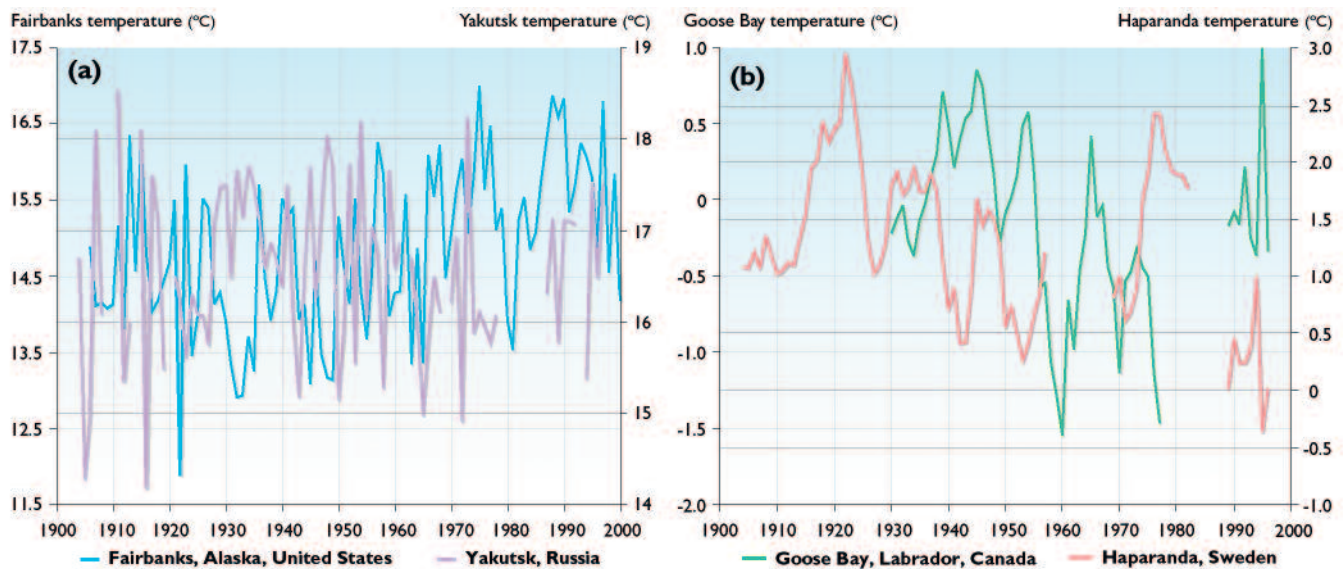
In addition to long-term trends and magnitudes of temperature increase, the models produce different features of shorter-term climate variability. Often these short-term climate events or minor trends can be decisive ecological influences. For example, even one or two years of high temperatures can be enough to produce extreme risk of forest fire (Johnson, 1992) or optimal conditions for major outbreaks of insects that kill trees or reduce their growth (section 14.8). Conversely, cold spells during the growth season may harm or kill the trees. A short-term period of favorable weather may trigger production of especially large tree seed crops, with long-lasting ecological consequences (Juday et al., 2003). The stations used for scenario analysis exhibit the opposite temperature relationships mentioned in section 14.2.4 (Fig. 14.7). When summer (June–August) temperatures are high at Fairbanks, Alaska (western interior of North America) they tend to be low at Yakutsk, Russia (eastern interior of Eurasia) (Fig. 14.7a). When mean annual temperatures at Goose Bay, Labrador, Canada (eastern edge of North America) are high, they


Fig. 14.7. Opposing temperature relationship between stations located in eastern and western portions of the continents in (a) summer (Jun–Aug) and (b) annual (5-yr running mean) (data from the Climatic Research Unit, University of East Anglia, United Kingdom, 2003).

tend to be low at Haparanda, Sweden (western edge of Eurasia) (Fig. 14.7b).

Because these features of climate variability are so important in producing ecological effects, it is important to understand the behavior of the models with respect to key features of short- and medium-term variability and seasonality.

Most of the ACIA-designated model outputs for the grid cells examined reproduce something close to the historical record of the difference between summer and mean annual temperature (Figs. 14.6 and 14.8a,c,d,e). However, sometimes scenario outputs show a different relationship between summer (May–August) and mean annual temperature than do the recorded data (Fig. 14.8b). All the model scenarios shown in Fig. 14.8 project temperature increases that are likely to substantially alter the moderately temperature-limited forest climate typical of the 20th century. The models project temperature ranges that would surpass thresholds for key factors such as outbreaks of insects that attack trees, new species, and altered ecosystem functions such as growth, fire, and decomposition.

The CGCM2 projections for the grid cell containing Fairbanks, Alaska, do not reproduce the same relationship between temperature trends in the coldest winter months and mean annual temperature as the recorded data (Fig. 14.9), and this disparity widens with time. It is possible that climate change would actually produce such an effect, but not all the scenarios agree on such features and realistic projections of effects on forests and agriculture require the resolution of such discrepancies. Different models have different strengths and weaknesses and all should be applied with an awareness of their limitations, circumstances in which they perform well, and novelties that could affect assessments of key climate-dependent processes. Differences in the relationship between seasonal and

annual climate variables can have particular ecological importance. For example, a higher growing-season temperature may increase the growth of trees, leading to one set of effects, but an increasing mean annual temperature may promote thawing of permafrost, which could undermine or destroy the soil rooting zone for trees growing on such sites. Thus, different rates of temperature increase (annual versus seasonal) may produce quite different ecological effects.

14.4.5. "Surprises" in climate change effects

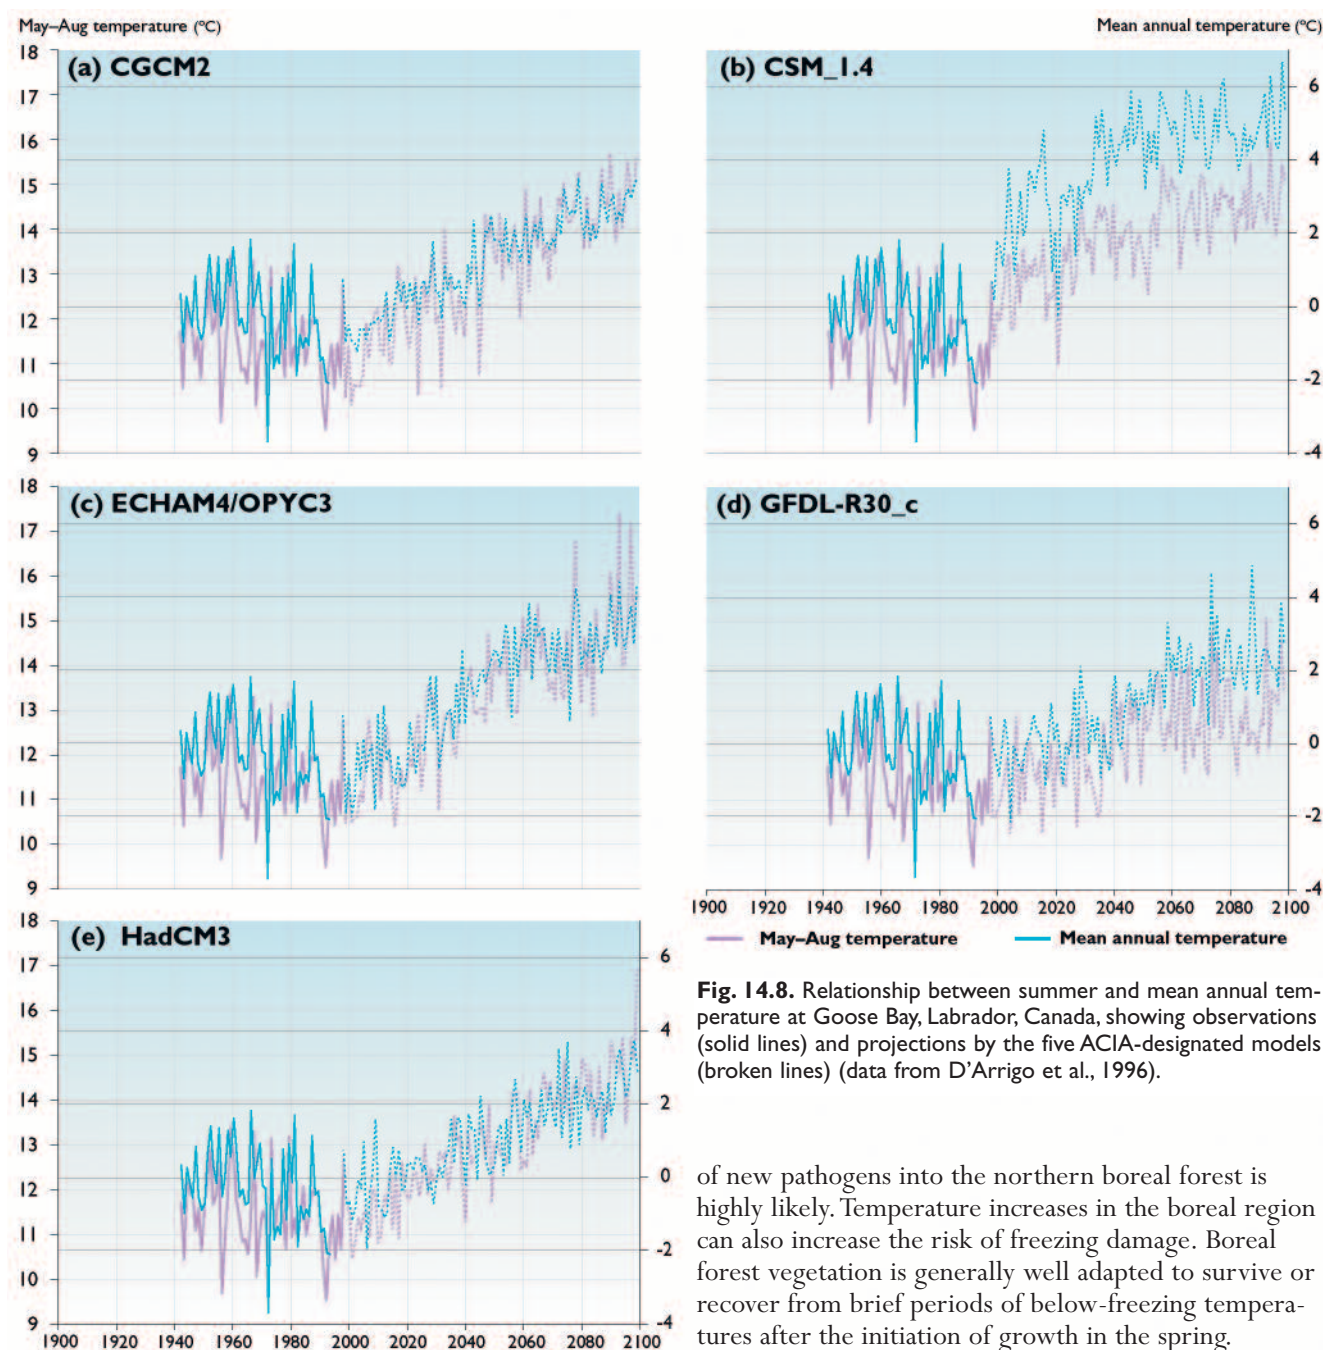
As with any use of models to project the future, a note of caution must be introduced. The projections of climate change and impacts on forests, land management, and agriculture are only as good as the climate models upon which they are based. It is also important to understand that the consequences of change introduced into ecosystems often include elements of chance and contingency that have very real and long-lasting consequences. Even though ecological events *could* unfold in a variety of ways under a given climate scenario, when events *do* take a certain pathway of cause and effect, this closes off another set of outcomes from that point onward. These elements of chance and contingency make it difficult to project ecosystem responses. However, other elements can assist in the projection of ecosystem responses. Including large areas in the analysis allows processes that have a variety of potential outcomes (e.g., the number of trees of a certain species reproducing successfully after a fire) to occur repeatedly. Any process that expands the pool of possible outcomes (either simulated outcomes or those that can be measured in ecosystems) of the climate change "experiment" will then cause the results or outcomes to begin to approach some distribution that may be described. Repeated outcomes can be produced not only as the result of multiple examples across space, but as the result of multiple outcomes across time in the same place. As a result, when larger areas and longer periods


Fig. 14.8. Relationship between summer and mean annual temperature at Goose Bay, Labrador, Canada, showing observations (solid lines) and projections by the five ACIA-designated models (broken lines) (data from D'Arrigo et al., 1996).

of analysis are involved, the outcomes in ecosystems can be better described.

The climate changes that are the most difficult to project are low-probability, high-impact events. By definition, there are few examples of such events to learn from; in fact, analogous events may not have occurred during the period of the observational record. An example in forest ecosystems is the introduction and spread of tree pathogens such as insects or fungi. Newly introduced pathogens are capable of radically reducing the abundance of susceptible trees, with long-lasting consequences, yet there is no direct human experience of such events and no evidence of the influence of such outbreaks in the past. Temperatures maintain the current distribution limits of many of these insect and disease pathogens, so if temperatures increase, then movement

of new pathogens into the northern boreal forest is highly likely. Temperature increases in the boreal region can also increase the risk of freezing damage. Boreal forest vegetation is generally well adapted to survive or recover from brief periods of below-freezing temperatures after the initiation of growth in the spring. However, some of these freeze-protection mechanisms provide protection from temperatures only slightly below freezing or are not fully effective at the earliest stage of growth. Earlier initiation of growth in the spring or even in the late winter in the boreal forest as the result of increasing temperatures is very likely to be followed by a return to seasonal cold temperatures well below freezing, resulting in damage that would not occur with later emergence from winter dormancy (Kellomaki et al., 1995, Prozherina et al., 2003). The upper levels of temperature increases projected by the five ACIA-designated models are within the range of climate change that is likely to include "ecosystem surprises" for which no historic analogue exists and which ecological modeling is not likely to project.

However, humans are not passive spectators of change in forest ecosystems or forest resources that are important to them. Humans actively intervene, plan, and
Fig. 14.9. Observed (solid line) and projected (CGCM2; broken line) winter and mean annual temperature at Fairbanks, Alaska. Observed data are a combination of University Experiment Station (1906–1948) and Fairbanks Airport (1948–2001) measurements (data from NOAA, 2002).

manage forest resources and agents of change in forests through their influence on factors such as fire that affect forests and forest values. Humans completely plan and create agricultural crops, livestock herds, and marketing systems. Therefore, it is possible for climate change to initially create effects that humans can respond to in a way that makes humans the most important agent of change. In some ways, these management responses are part of the standard set of land and resource management treatments that forestry and agriculture have developed over time. Reforestation, new species plantations, salvage of dead trees, sanitation treatments of a stand to reduce its vulnerability to pathogens, planting new crops, and altering soil or site conditions have a long history. Crops can be moved to suitable temperature zones, fields irrigated, and tillage systems adjusted to manipulate soil temperature within certain limits. What is new, and only now being developed, is the application of these techniques and the development of additional techniques to achieve specific goals associated with climate change in the far north, including both adaptation and mitigation approaches, and some appreciation of the associated costs.

14.4.6. Differences between the B2 and A2 emissions scenarios

For all of the model analysis presented in this chapter, projections based on the B2 emissions scenario (section 4.4.1) were used. This section evaluates the possible differences between model projections based on the A2 emissions scenario and those based on the B2 emissions scenario.

Broadly speaking, all the ACIA-designated models forced with either emissions scenario project that temperatures within the boreal region will reach levels higher than shown by reconstructions of climate for nearly the last 1000 years or essentially since the Medieval Warm Period. In every case, the models forced with the A2 emissions scenario project higher temperatures at the end of the 21st century than they project when forced

with the B2 emissions scenario (section 4.4.2). The temperature increase over the 21st century projected by the model with the least warming when forced with the B2 emissions scenario (CSM_1.4) is about 3.5 °C, but the same model when forced with the A2 emissions scenario projects a temperature increase of about 4.5 °C over the same period. The greatest temperature increase over the 21st century – slightly more than 7 °C – is projected by the ECHAM4/OPYC3 model forced with the A2 emissions scenario.

Considered from the broadest perspective, the difference between projections based on the A2 emissions scenario versus those based on the B2 emissions scenario is largely a matter of timing of effects on forests rather than different kinds of effects. In practical terms, this means that the thresholds described in this chapter would be reached sooner under climate conditions projected using the A2 emissions scenario compared to conditions projected using the B2 emissions scenario. The difference in timing of these effects is projected to be as much as 40 years earlier in the case of the projections based on the A2 emissions scenario. The temperature projections of each model when forced with the A2 emissions scenario begin to diverge from projections using the B2 emissions scenario in amounts significant for forest processes after about 2040.

In general, the projections of the ECHAM4/OPYC3 model forced with the B2 emissions scenario best matched the features of annual temperature variability in the recorded data for the stations examined in this chapter; most of the other four scenarios produced less annual variability. The ECHAM4/OPYC3 model forced with the A2 scenario projects a pattern of steep temperature rise early in the 21st century, then a period of little change, and finally a steep rise again in the last decades of the century. This suggests that the effects of climate change under this scenario, with large variability possible from year to year, could be especially sudden. Under such a scenario the risk of extreme events, such as widespread forest fires and insect outbreaks, would probably be greatest.

14.5. Agriculture

14.5.1. Arctic agriculture in a global context

The population of the earth relies on two basic agricultural systems for its food supply. The first is the *large-scale commercial production* and trade of commodities. The commodities that dominate this system are cattle, sheep, and hogs for meat or wool, dairy animals for milk products, grains for animal feed and direct human consumption, and oilseeds. These products move through a complex, and in most cases efficient, network of trading, transportation, and processing before reaching the final consumer. Smaller volumes of products that are important for human dietary variety also move through this network, including potatoes, fruits and vegetables, and raw products for beverages and spices. As a result, a diverse array of foods is available to those

consumers who have both physical and economic access to the network. Within the Arctic, this agricultural and trading system serves major population centers, areas served by regular surface transportation, and remote communities. The potential impacts of climate change on this system are global and complex: the system is vulnerable to direct climate influences on crops in multiple climate zones across the earth, to direct climate effects on shipping activities, and to subtle climate influences on prices and relative price differences (Rosenzweig and Parry, 1994).

The second type of agricultural system that supplies food for the population of the world is *subsistence* agricultural production. This system can be generally characterized as regional and largely self-reliant. It does not rely on a complex infrastructure to move either raw or manufactured products to the final consumer. Products are characteristic of the production region, and often obtained as part of a mixture of annual activities (section 12.2.2). These regions are categorized as those having low population density and/or a low economic profile. This subsistence agricultural system serves the majority of the area of the Arctic, but a minority of its population. Generally, regions in which subsistence agriculture predominates have either limited or no physical and/or economic access to the primary global food supply network. Potential climate change impacts on the subsistence system may be acute and local (e.g., a mid-season frost kills a crop) or subtle and longer term (e.g., climate effects on price advantages or barter opportunities).

In the Arctic, many examples can be found of a mixture of the two food systems or a cultural preference for the subsistence agricultural system despite economic and infrastructure advantages that would permit participation in the commercial production system. People in the Arctic can and often do move between participation in one system and the other. It is not clear that the commercial production system will completely displace the subsistence agricultural system in the foreseeable future.

14.5.2. Existing agriculture in the Arctic

Agriculture is a relatively small industry in high-latitude regions and consists mostly of cropping cool-season forage crops, cool-season vegetables, and small grains; raising traditional livestock (cattle, sheep, goats, pigs, poultry); and herding reindeer. This chapter focuses on crop production rather than livestock. Production of inexpensive reliable feeds is often a major constraint to animal agriculture and livestock production is often limited more by non-climate factors such as availability of processing facilities and appropriate waste handling rather than directly by climate. While agriculture is limited by climate in the Arctic, especially in the colder regions, it is also limited by lack of infrastructure, a small population base, remoteness from markets, and land ownership issues. Major climate limitations include short growing seasons (not enough time to mature or to produce high yields of harvestable crop), lack of heat energy (too few

GDDs during the season), long and/or unfavorable winter weather that can limit survival of many perennial crops, and high moisture stress in some areas.

Most of the climate stations selected for examination have climates that are currently at least marginally suitable for growing barley, oats, green peas, and potatoes (although not always to full tuber maturity). Wheat has been grown in experimental plantings as far north as Rovaniemi, Finland, the southern Northwest Territories, Canada, and Fairbanks, Alaska, but is considered too marginal for commercial production in those areas and is a major commercial crop only in southern Siberia (represented by Novosibirsk). Canola (rapeseed) is also produced only in the southernmost part of the Arctic and is considered marginal even in many areas now considered suitable for barley (such as Interior Alaska). Sunflowers currently are produced in generally the same locations as wheat. The magnitude of temperature increases projected by the ACIA-designated models would remove these heat limitations in areas that are presently climatically marginal by the mid- or late 21st century.

All of the climate stations examined in this chapter have summers with enough heat to produce at least one successful harvest of forage crops, including legumes such as alfalfa or clover and grass such as timothy. Slight increases in growing-season temperature are likely to increase the probability of two or more successful harvests and thus increased yields in some areas. However, winter survival is a problem in most areas, thus alfalfa is produced only in the warmer parts of the Arctic, and clovers are successfully grown in areas with relatively mild winters. Perennial grasses, especially smooth bromegrass and timothy, are grown in much of the region.

Agricultural production statistics match the boundaries of the Arctic as defined in this chapter at the national level for Iceland. Relevant statistics are also available for the three northern counties of Norway (Troms, Finnmark, and Norland), Alaska (United States), and the Yukon and Northwest Territories (Canada). These areas are highlighted in this section. Data from the Norrbottens region of Sweden match this chapter's analysis area, and Finnish agricultural statistics are readily available at the national level and for jurisdictions with boundaries that are not as relevant for the purposes of this assessment. Complete and reliable statistics for agriculture in arctic Russia are not available.

Yukon Territory is one of the most mountainous parts of Canada, but agriculture occurs in valleys, especially in the southern interior, and in suitable landforms in the Northwest Territories. The data in this section on Canadian agriculture are from Statistics Canada (2001) and Hill et al. (2002). There are at least 170 farms in the Yukon and 30 in the Northwest Territories, representing a total capital value of over Can$ 67 million, primarily in land and buildings. Most of these farms are operated as part of a yearly cycle of other activities, and only 21 have gross receipts greater than Can$ 25 000.

Farmers in the Canadian north take a diversified approach to agriculture. They produce traditional livestock and engage in sled-dog breeding and non-traditional livestock production primarily for local and specialty markets. Along with east-central Alaska, the western Yukon is the driest part of the North American subarctic. Because portions of these regions are already natural grasslands too dry for tree growth, irrigation would certainly be required to exploit improved temperature regimes for crop agriculture in such areas. In the central and eastern Canadian Arctic, temperatures currently fall well below minimums necessary for traditional agriculture, although warming trends have been detected. Across much of the Canadian far north, further temperature increases as projected by the ACIA-designated models would move the zone of temperature suitability northward into a region largely dominated by soils with relatively poor suitability for agriculture. Broad areas of Turbic and Organic Cryosols cover these northern landscapes (Lacelle et al., 1998), and in the glaciated north, soils are often thin, stony, and derived from nutrient-poor bedrock parent materials. Areas with pockets of suitable climates and soils that are close to population centers could possibly become locally important for food production for established populations with a goal of greater self-sufficiency.

Alaska has several climatically distinct agricultural regions, including interior valleys and lowlands with warm and dry summer climates, coastal regions with cooler summers and moderate to high precipitation, and a broad transition region in the major population zone of south-central Alaska. Most of the volume and value of agricultural production takes place in the transition and interior locations. In the dry interior valleys, heat sums necessary to mature grains such as barley are generally achieved, and recent warming trends have increased the probability of achieving this critical factor to a very high level (Sharratt, 1992, 1999). In interior valleys and the south-central transition region, there is a high correlation between years of excellent crop production and adequate and (especially) well-timed precipitation in the early and middle parts of the growing season. However, persistent and heavy precipitation in the late summer can delay, reduce, or even ruin crop harvest and recovery.

In 2001, Alaska had about 580 farms and ranches (sales greater than US$ 1000) covering 370 000 ha, of which the great majority was unimproved pasture (Alaska Agricultural Statistics Service, 2002). Alaskan crop production in the same year included 10 500 t of potatoes (including high-value, certified virus-free seed potatoes), 27 000 t of hay, 800 t of carrots, and over 8800 m³ of oats and barley. Alaska produced 11 500 cattle, 1200 sheep, 1000 hogs and 15 000 domestic reindeer in 2001. A few farm and ranch operations are producing species such as elk (wapiti), bison, yak, and musk oxen. Some Alaskan crops and pastures are already moisture-limited, especially in the warmer summer climate of recent years (Sharratt, 1994). If temperatures were to increase across

the northern boreal region without a significant increase in precipitation in the early and middle parts of the growing season, the change would be unfavorable for agricultural production, except in the case of irrigated crop production that could take advantage of the greater growing-season heat units. Temperature increases projected for coastal areas generally are very likely to be favorable to agriculture, although much of the area consists of steeply mountainous terrain with little soil development. In the south-central transition region, Alaskan agriculture faces strong economic challenges from competing urban and suburban land uses in the region where historically it has been most well-established. Large new areas are available to be opened to agriculture, especially in central Alaska, but no recent public policy initiative to do so has emerged. National-level agricultural subsidy payments to Alaskan farmers have nearly doubled in the last decade to over US$ 2 million, or about 20% of net farm income.

In 2000, northern Finland contained about 10 000 farms, of which about 50% were dairy farms. The average farm size is about 11.5 ha. While most northern Finnish farm properties remain in their traditional size and configuration (they have not been subdivided), the number that are producing significant amounts of dairy products has decreased rapidly in recent years (Häkkilä, 2002). Reasons for the decline include surpluses of dairy products, small quantities produced, and especially social change. These changes include migration of farm owners to towns and cities with professional opportunities that are more attractive and have higher income potential, and the conversion of inactive farms into country residences for town dwellers.

The three northern counties in Norway had 95 000 ha of land in agricultural use in 1999, distributed among about 6500 owners (Statistics Norway, no date). The area receives nearly the maximum warming influence of the Gulf Stream in the Arctic, so there is a strong maritime influence especially in the south and west of the region. Climate factors limiting to agriculture are maximum temperatures and total warmth over the summer,

Fig. 14.10. Garden in northern Norway (photo: P. Grabhorn, 2003, Grabhorn Studios, Cerrillos, New Mexico).

which are strongly influenced by cool and wet maritime weather. Prolonged cool and wet maritime conditions can result in slow plant growth and failure of crops to complete development, wet fields and crops at harvest time, and, occasionally, outbreaks of plant diseases. Agricultural operations are generally small, with only 570 holdings larger than 30 ha and only 50 holdings larger than 50 ha. Employment in agriculture, horticulture, and forestry in the three-county region in 1999 totaled about 6500 full-time equivalents. Many of these farming operations fit into a diversified set of annual activities that include wage employment, fishing, cultural landscape maintenance, and personal consumption and non-cash trade of crops (Fig. 14.10). Nearly all farming operations include cultivated meadows for hay and pasture, and about one-third produce potatoes. Only 45 farms, all in the southernmost county of Nordland, produce grain or oilseed crops.

Temperature increases are likely to move the grain production boundary northward. Any climate changes that enhance the maritime effect, especially in the summer, would not be favorable to agriculture in this coastal region, although the effects are very likely to be lessened inland. Climate changes that increase growing-season length and daily maximum temperatures while maintaining or slightly decreasing persistence of growing-season clouds and rain are very likely to be favorable to agricultural production in this area. Agriculture in the far north of Norway will be strongly influenced by national and European policies to subsidize rural populations and landscapes, perhaps more than any other factor. The government of Norway is likely to have sufficient revenues available from petroleum to intervene strongly in the economics of northern community infrastructure and agriculture to achieve its social and environmental goals for some time to come.

Iceland is surrounded during the growing season by a cool ocean surface; locations farthest inland from the cool maritime influence are covered with glacial ice. As a result, lack of summer warmth has been the chronic limitation to Icelandic agriculture, especially in years when sea ice reaches the Icelandic shoreline. Icelandic agriculture traditionally has been limited to the crops most tolerant of cool season conditions. Even small temperature increases historically have removed this limitation and permitted the better harvests in the record. Iceland produces over 2 million m³ of hay, more than 10 000 t of potatoes, and over 4000 t of cereal grains (barley; Statistics Iceland, 2003). Glasshouse agriculture using abundant geothermal heat supports the production of about 1000 t of tomatoes and cucumbers. In 2001, the 3000 farms in Iceland produced 473 000 sheep, 70 000 cattle, 73 000 horses, and 106 000 liters of processed milk (Statistics Iceland, 2003). During the last decade of the 20th century, sheep and hay production declined at double-digit rates, largely for non-climatic market, policy, and social reasons. Numbers of cattle and horses (the famous Icelandic pony) have remained level. Icelandic agriculture employs about 4400 people, which

is 3.1% of the total employment. Greenland supports about 20 000 sheep and more than 3000 reindeer (Statistics Greenland, 2005).

The entrance of Iceland into the European Community Common Agricultural Programme (CAP) has been the major force in Icelandic agriculture in the last decade. In general, CAP subsidies have sustained smaller and higher-cost producers and rural economies, introduced limitations for certain products, reduced risk to producers, and transferred funds from consumers to producers. Temperature increases would almost certainly permit accelerated expansion of cereal grain production and possibly new oilseed crops, reduce the cost of winter forage for livestock, and allow increased per-unit crop yields where nutrients or water are not limiting. There are complex multiple goals in Icelandic agriculture, including food production, employment, rural stability, maintaining an attractive landscape, and environmental protection. Because the agricultural system exists in a highly interventionist public policy environment, a traditional economic analysis is likely to show that national and CAP policies will be more influential than temperature increases in the future of Icelandic agriculture (see section 14.3.4.4 for a discussion of the conversion of agricultural land to forests).

14.5.3. Approach to scenario analysis

The 14 sites that were chosen for examination of the ACIA-designated model projections were selected to represent areas in the northern part of the boreal region currently supporting commercial agriculture and areas north of current potential (section 14.4.1). The analysis did not consider soil effects, although soil can be a major limitation to agriculture, and changes in soil processes following climate change can have significant impacts on agriculture (Gitay et al., 2001). In much of the circumpolar north, large tracts of soils already exist that are suitable for agriculture if other constraints are removed, with the exception of much of northern Canada (composed of the Canadian Shield) and northern Fennoscandia, where the granitic soils are shallow and nutrient-poor.

This analysis used GDDs as a primary determinant of climate suitability for producing annual crops. Growing degree-days (a measure of accumulated heat energy) are considered a good predictor of plant phenology and are often used to project the timing of different plant growth stages. For example, farmers and extension agents often use GDDs to determine the optimum harvest time for forage crops. There are some major limitations to the use of GDDs. They may vary for different cultivars, locations (Sanderson et al., 1994), and growth stages (Bourgeois et al., 2000; Kleemola, 1991). Heat energy requirements for plants interact with other environmental factors, such as moisture stress and photoperiod (Bootsma, 1984; Nuttonson, 1955, 1957), and thus GDDs may not be a good predictor of plant development under stress. Heat requirements for plant development generally decrease with increasing photoperiod,

so fewer GDDs are needed to reach a given growth stage at high latitudes than at low latitudes.

In areas with humid autumns, GDDs may equal or exceed the threshold for a given crop to reach maturity, but wet conditions may not allow the crop to dry enough to allow cost-effective mechanical harvesting. Thus, even though projections of future temperature may indicate that certain areas will be suitable for some crops, wet conditions may offset the temperature effects, especially in more humid zones within the northern boreal region.

Growing degree-day requirements for various crops from the highest-latitude areas possible were obtained from the literature, and similar GDD requirements were assumed for a given crop throughout the region. One problem with using GDD data from the literature for determining climate suitability for a given crop is that different reports use different base temperatures for calculating GDDs. For example, many agriculturists often use a base of 5 °C (GDD_5) for cool-season crops, while others use a base of 0 °C (GDD_0). Others use some experimentally determined growth threshold as the base temperature. If no information existed for GDD requirements using a base of 5 or 0 °C, the GDD requirements for the base temperatures of interest were estimated from published GDDs based on similar base temperatures. In some cases, insufficient information was available to do this for both 5 and 0 °C base temperatures. Despite its limitations, use of GDDs is a widely reported and accepted method to project approximate crop phenology. GDD analysis is generally accepted as a good way to estimate climate suitability for producing annual crops.

For projecting potential water stress, the analysis used model-projected potential evapotranspiration minus growing-season precipitation. Positive values indicate a potential water deficit, interpreted to mean potential water stress, which could limit crop yields or quality. However, many crops can produce acceptable yields even under water-deficit conditions, and water stress is also affected by soil water-holding capacity, rooting depth, precipitation timing (e.g., spring versus summer), and type of storms (e.g., infrequent large rainfall events may result in more water loss due to runoff than small, frequent storms).

This assessment ignored the effects of atmospheric CO_2 enrichment and changes in crop pests, other than to estimate the potential general effects. Few field studies have been done on CO_2 enrichment effects on crop plants at high latitudes and results from more temperate zones may not be transferable to northern areas, thus there is little data on which to judge the effects of CO_2 enrichment. Climate effects on pests are complex and difficult to forecast. Such an analysis is obviously needed to understand the complete range of climate change effects, but it is not yet feasible because of a lack of detailed knowledge of insect and other pathogens.

For this analysis, a few annual crops were selected that are currently well-adapted or marginally adapted to parts of the region and which have potential to become economically important crops for animal feed (cereal grains), human food, (beans, peas, potatoes, wheat), or oilseeds (canola, sunflowers).

14.5.4. Climate limitations and influences

If the ACIA-designated model projections of GDDs at a given site equaled or exceeded the minimum GDD requirements for a given crop, but were below the mid-point of the range given in Table 14.3, the crop was considered to be marginal. The analysis was based on 20-year averages, to smooth out much of the variability in the data and because it is assumed that farmers would require about 20 years under a changing climate regime to accept the change and adopt farming practices that included new crops.

The GDD requirements for some of the crops presented in Table 14.3 appear inconsistent between the two base temperatures (for example, with a base of 5 °C, seed peas appear to require fewer GDDs at the low end of the range than canola but require more GDDs at the upper end of the range). This may be due to errors in the literature, errors in the estimation of GDD requirements, or it may mean that either the 5 or 0 °C base temperature is not appropriate for some crops. This may cause errors in determining climate suitability for some crops. Table 14.3 also provides estimates of the number of accumulated GDDs required for forage crops to reach optimum time of harvest. These may be underestimates for high-latitude

Table 14.3. Growing degree-day requirements for various annual crops to reach maturity (Anon., 1996-2000; Ash et al., 1999; Dofing, 1992; Dofing and Knight, 1994; Juskiw et al., 2001; Miller et al., 2001; Nuttonson, 1955, 1957; Sharratt, 1999) and for forage crops to reach optimum harvest stage (Bootsma, 1984; Breazeale et al., 1999).

	Growing degree-days (5 °C base)	Growing degree-days (0 °C base)
Annual crops		
Peas (green for processing)	700–800	1000
Spring barley	700–900	1200–1500
Peas (for seed)	800–1150	1500–1700
Oats		1300–1700
Canola	950–1050	1350–1550
Potatoes	1000–1100	
Spring wheat	1000–1200	1400–1650
Dry beans	1100–1500	
Sunflowers (for seed)		1800–2000
Forage crops		
Alfalfa	350–450	
Red clover	450

regions, as low soil temperatures may delay initiation of growth, especially in spring.

The models use large grid cells, which often contain large tracts of terrain not likely to become suitable for agriculture (such as high mountains), and some of the model projections are obviously not realistic even for present conditions. Therefore, this analysis uses proportional changes from the present, compared to observed weather data, rather than using actual temperature projections provided by the models. For each parameter analyzed (GDD_0, GDD_5, and growing-season water deficit), the highest and lowest projections for each location were selected (Table 14.4).

The success of perennial crops is governed more by winter survival success than by growing-season weather conditions. Factors such as the timing of killing frosts, warm spells during winter, length of the dormant season, snow

depth, and winter temperatures all interact to affect winter survival. Warm periods during winter, especially prolonged temperatures above 0 °C, can be detrimental to perennial plants by reducing winter dormancy and depleting carbohydrate reserves (Crawford R., 1997). The complexity of these interactions makes projection of climate change effects on these crops difficult.

14.5.5. Growing degree-day analysis

When GDD_0 was used for analysis, all of the ACIA-designated models projected that all the examined locations would be suitable for green pea production early in this century, and the high-extreme models (GFDL-R30_c and CGCM2) projected climates suitable for barley at all locations by 2030. When GDD_5 was used, the models projecting the most GDDs suggested that Reykjavik and Tromsø would be unsuitable for green peas by 2030 because of too many GDDs. The GFDL-R30_c projections indicate that potatoes could be grown in all locations except Reykjavik, Tromsø, Rovaniemi, and Magadan (marginal at Umeå and Archangelsk) by 2030, while the low-extreme models (HadCM3 and CSM_1.4) projected suitable climates only in Fairbanks, Fort Vermillion, Thompson, Goose Bay, Novosibirsk, and Yakutsk. Thus, projections for potatoes may be too low, as potatoes are already produced, at least marginally, in many areas not projected to be suitable by 2030. This may be because use of GDDs may not be a good way to project phenological development in potatoes (Shaykewich and Blatta, 2001). The models generally projected that all except the coolest sites in Scandinavia would have climates at least marginally suitable for potato production by the end of the century.

All of the models project a climate suitable for dry pea production at all locations except Reykjavik and Tromsø by 2030 when GDD_5 was used, although the low-extreme models (HadCM3 and CSM_1.4) projected that Goose Bay, all of the Scandinavian sites, Archangelsk, and Magadan would be unsuitable for dry peas using GDD_0. All the models project that all sites except Reykjavik and Tromsø would have climates suitable (marginally so at Goose Bay) for seed pea production by the end of the century. The high-extreme models (GFDL-R30_c and CGCM2) project that all of the North American sites (marginal at Big Delta, Whitehorse, and Goose Bay), Novosibirsk, and Yakutsk would have climates suitable for dry bean production by 2030, but the low-extreme models (HadCM3 and CSM_1.4) project that climate would only be marginal for such production even at the warmest sites (Fairbanks, Fort Vermillion, Thompson, Novosibirsk) by 2030. Models projecting the highest number of heat units at a given location indicated that all sites except Reykjavik, Tromsø, and Rovaniemi would be at least marginally suitable for dry beans by 2060, whereas the low extreme models (HadCM3 and CSM_1.4) indicated that only Fairbanks, Fort Vermillion, Thompson, Goose Bay, Novosibirsk, and Yakutsk would have climates suitable for dry bean production by 2090.

Most of the models projected that most locations would be at least marginally suitable for all of the cereal grains by the end of the century, although the low-extreme models, using GDD_5, projected that only Fairbanks, Fort Vermillion, Thompson, Goose Bay, Novosibirsk, and Yakutsk would be well-suited for wheat by 2090. The high-extreme model (GDFL-R30_c or CGCM2) for each location projected that climate would be suitable for canola at all locations except Tromsø by 2030 using GDD_0. All of the models projected that climate will be at least marginally suited for oilseed sunflowers by 2030 at Fairbanks, Thompson, and Novosibirsk, and the high-extreme models projected climates suitable for sunflowers at all sites except Goose Bay, Reykjavik, and Tromsø (marginal at Rovaniemi) by 2090. Conversely, the low-extreme models projected that only Fairbanks, Thompson, Novosibirsk, and Yakutsk would be well-suited, and Big Delta and Fort Vermillion would be marginally suited, for this crop by near the end of the century.

Assuming that the amount of heat is the main factor limiting yields and number of harvests of perennial forage crops, model projections indicate that warmer growing seasons are likely to increase the potential number of harvests and hence seasonal yields for perennial forage crops at all locations. Uncertainty about winter conditions make forecasts about survival potential for crops difficult. Warmer winters could actually decrease survival of some perennial crops if winter thaws followed by cold weather become more frequent. Crops adapted to certain types of winter stress are very likely to experience different types of stresses if winter temperatures rise and winter thaws become more frequent. However, lengthened growing seasons, especially in autumn, are very likely to result in northward extension of climate suitable for alfalfa production.

Table 14.5. Projected water deficits calculated from highest and lowest model projections at each site. Negative values indicate a water surplus.

	Water deficit (mm)					
	2011–2030		2041–2060		2071–2090	
	Highest	Lowest	Highest	Lowest	Highest	Lowest
Fairbanks	250	166	282	207	311	253
Whitehorse	150	116	287	165	321	265
Fort Vermillion	324	148	355	168	371	218
Thompson	335	132	394	157	413	169
Goose Bay	22	-122	62	-151	58	-125
Reykjavik	184	-20	216	-15	241	68
Tromsø	84	-31	117	14	134	44
Umeå	217	139	250	163	262	173
Rovaniemi	185	51	233	111	226	145
Archangelsk	191	-7	232	26	231	31
Novosibirsk	389	126	414	127	469	149
Yakutsk	289	152	315	161	328	165
Magadan	224	117	238	164	269	180

All of the models project high interannual variability in GDD accumulation. Thus, even though 20-year averages may indicate climates well suited for crops for a given area, the frequency of growing seasons cool enough to limit production may convince farmers that the risk for producing these crops is too high. Thus, the perception of risk by farmers could be a limiting factor for the northward advancement of many of the analyzed crops.

14.5.6. Precipitation and potential evapotranspiration analysis

Most of the models project increases in precipitation at most locations, with some forecasting up to 20% increases from values typical of the 1981–2000 baseline period by 2090. There was a great deal of variability among models, with no single model consistently projecting the greatest or smallest change in precipitation at all locations. A few models projected decreases in precipitation at a few sites. For example, CSM_1.4 projects a decrease of 5% at Whitehorse (compared to the present) during the 2011–2030 time slice, and HadCM3 projects a decrease of about 1% at Umeå and about 4% at Tromsø by 2090. All models projected a general increase in potential evapotranspiration over time at all locations, with much variability among models and locations.

Some locations in the subarctic already experience water deficits large enough to reduce crop yields. For example, Sharratt (1994) found that barley yields in Interior Alaska are depressed in about five of every nine years due to insufficient water supply. Water deficits were usually projected to increase over time, with GFDL-R30_c usually projecting the smallest deficits and HadCM3 and CSM_1.4 usually projecting the largest (Table 14.5). Most models project rather large water deficits, especially by the end of the analysis period. However, the HadCM3 model projects rather large water surpluses throughout the 21st century at Goose Bay, and slight surpluses at Reykjavik until about mid-century (Table 14.5). Most models, especially CSM_1.4, project fairly small deficits at Tromsø. These results indicate that water is likely to become a major limiting factor for production of most crops at all but the maritime sites in the boreal zone. Unless irrigation is supplied, which may not be economical for most of the crops analyzed, production is likely to be limited in many areas to drought resistant crops, such as cereal grains.

14.5.7. Indirect effects of climate change

This analysis has focused on the direct effects of changes in growing-season temperatures (using GDDs as indicators of crop growth potential) and moisture relationships on potential agricultural crop production in the next century in high-latitude regions. However, the indirect effects of climate change may have similar or greater impacts on agricultural development. Several of them are outlined here without in-depth analysis, to acknowledge their potential importance

and alert those involved in future assessments that these factors need to be considered.

The development of crop disease requires suitable host, pathogen, and environmental conditions. Temperature and moisture are critical for the spread of many plant diseases (Gitay et al., 2001), especially in a region as severely heat-limited as the Arctic. Under conditions of increasing temperatures, the risk of crop damage increases in all regions of the northern half of Europe (Beniston et al., 1998). The severity and number of species capable of reaching infestation levels for North American agriculture are likely to increase with less severe winters (Shriner et al., 1998). These findings suggest that disease and weed pests are likely to increase throughout the Arctic under the ACIA-designated model scenarios. These problems are not likely to offset potential yield increases or eliminate the potential for new crops in most cases. However, it is possible that severe outbreaks could have that effect in specific cases. For example, temperature increases in Finland are very likely to increase the incidence of potato late blight to the point that it will significantly decrease potato yield in that country (Carter et al., 1996).

While the effects of atmospheric CO_2 enrichment were not considered in this analysis, higher CO_2 concentrations are very likely to result in yield increases for most crops (Warrick, 1988). Lack of experimental data on the effects of CO_2 fertilization on crops in high-latitude regions make in-depth analysis of this effect impossible at present.

Lack of infrastructure development, small population sizes (thus limiting local markets), and distance to large markets are likely to continue to be major factors limiting agricultural development in most of the northern part of the boreal region during this century. One possible indirect effect of climate change on agriculture in the Arctic and subarctic is the effect on transportation, including land transport and the prospect of regular ocean shipping across the Arctic Ocean with reduced or absent sea-ice cover (section 16.3). Thawing of permafrost that is susceptible to ground subsidence is disruptive to existing roads and railroads. Ultimately, once the permafrost thaws, in nearly all cases a more stable foundation will be available for permanent transportation routes and facilities. It is possible that shipping across the Arctic Ocean will greatly enhance economical trade in agricultural products, especially products unique to these regions, and thus enhance development of commercial agriculture in the far north.

If the net effect of climate change is greater global agricultural production, then food prices are likely to be lower for the world as a whole as long as the rather large subsidies that influence prices do not markedly increase or decrease. Lower world food prices would reduce the incentive to rely on local commercial or subsistence production in the Arctic. The opposite would be the case if climate change reduces global agricultural production.

A key component of the ability of global food production to cause a fundamental change in the supply/demand relationship for local agricultural production in the Arctic (other factors being equal) is shipping cost. Regular shipping across an ice-free Arctic Ocean (section 16.3.7) is very likely to lower transport costs for non-perishable bulk commodities such as grains or fertilizers, and thereby lower prices for the basic inputs to the agricultural system in the Arctic. In addition, it is possible that the availability of arctic shipping will stimulate the export of bulk finished products from the Arctic. The volume of agricultural imports to or exports from the Arctic is unlikely to generate the economies of scale that would support regular shipping at a major cost advantage for agriculture within the Arctic, at least not within the 21st century. Mining and petroleum industries would be more likely to generate higher volumes of cargo, although there is only a limited ability to change the kind of cargo handled by specialized vessels. However, if arctic ports of call were integrated into a much higher volume of general trade between the northern continents, then price advantages for agriculturally related arctic cargoes would be much more likely.

The impacts of lower transport cost on arctic commercial agricultural production would be complex. Inexpensive, regular arctic shipping is very likely to provide a price advantage that could possibly stimulate production of unique arctic commodities such as reindeer and caribou meat or muskox milk or cheese, as long as other factors affecting demand were favorable. Conversely, lower shipping costs are likely to discourage arctic production of agricultural commodities widely produced elsewhere, unless overall global supply or demand structure shifted descisively. However, basic input data that would permit in-depth analysis, including trade levels and patterns in an ice-free Arctic, economics and practicalities of Arctic Ocean shipping operations, and the overall regional costs of arctic agricultural production compared to global supply and demand, are somewhat speculative or lacking.

In Europe, the United States, and Canada, public policy and interventions are major factors that agricultural producers confront in determining their activities. In many cases, national or trading-area agricultural transfer payments and rules of production correlate especially well with the annual profile of agriculture in the Arctic, as noted in section 14.5.2. There is no obvious trend to suggest that the significant role played by government policy will change during the 21st century. Russia is experiencing a period of population and economic consolidation in its northern regions, an adjustment required after investments made during Soviet times could not be sustained under new conditions. Given the strong dominance of state land ownership, government policy will be a decisive factor in the future of agriculture in most of the arctic nations. The current agricultural profiles also suggest that local markets are vital to the agricultural sector in the Arctic. If climate change results in increases in the human population of the

Arctic, then the entire agricultural sector is likely to expand given the historic positive relationship between regional population and agricultural production.

14.6. Tree rings and past climate

The most recent historical period of Northern Hemisphere warming of similar magnitude (but possibly different in its cause) to that of recent decades is the Medieval Warm Period (MWP) from about AD 900 to 1300 (see also section 2.7.5). However, interpretations of the climate during the MWP do not always agree. Some evidence suggests that the MWP was not general across the planet and did not exceed the current warming in its fluctuations (Hughes and Diaz, 1994; Mann M. et al., 1998). Other evidence suggests temperatures 1 to 1.5 ºC higher than at present across the Northern Hemisphere during the MWP (Dahl-Jensen et al., 1998; Esper et al., 2002; Naurzbaev and Vaganov, 2000). The main tool to compare recent warming with temperature levels during the MWP and earlier periods in most terrestrial regions of the far north is long-term climate reconstructions based on tree-ring data, because few or no other historical records exist and marine proxies and ice cores cannot provide the required geographic coverage or detail.

Tree-ring chronologies serve as a useful basis for reconstructing natural temperature fluctuations in the high latitudes over millennial intervals, although the degree of reliability needs to be assessed carefully in each application. An important potential limitation is that the relationship between tree rings and climate may vary with time. However, compared to other indirect sources of climatic information, tree-ring chronologies have certain important advantages. First, tree rings record a complete annual sequence of climatic information. Second, in northern Eurasia, where trees reach a maximum age of 1100 years, there is a dense dendroclimatic network allowing spatially detailed quantitative temperature reconstruction for the last 500 to 600 years, and in some regions for more than two millennia (Briffa et al., 2001; Hughes et al., 1999; Vaganov et al., 1996, 2000).

The rate and magnitude of recent Northern Hemisphere temperature increases are unique within the last several centuries (Briffa et al., 1996, 2001; Mann M. et al., 1998). Some climate models that include anthropogenic effects calculate that the greatest temperature increase, in the range of 3 to 4 ºC, should have occurred over the last several centuries in the high latitudes of the Northern Hemisphere (Budyko and Izrael, 1987; Kondrat'ev, 2002). However, temperature reconstructions (generally of the warm season or even a specific portion of the warm season) based on tree-ring chronologies from subarctic Eurasia, a region that makes up a large part of the projected zone of maximum warming, do not show temperature increases of the projected magnitude (Briffa et al., 1998; Naurzbaev and Vaganov, 2000). This may be partly due to the disproportionate influence of warm-season temperatures

on tree growth, genuine local spatial climate variability, issues in calibrating the tree rings to estimate temperature with uniform reliability throughout the whole period of analysis, or errors or missing factors in climate model scenarios.

14.6.1. Past climate change in central Eurasia

This section examines several aspects of high-resolution proxy records based on tree-ring chronologies. Subarctic temperature reconstructions for Asia are compared with the main climatic forcing mechanisms during the last several centuries; reconstructed temperature fluctuations during the MWP are compared with recent temperature changes in the high latitudes of Eurasia using the millennial tree-ring chronologies; and recent temperature fluctuations are compared to temperature fluctuations during most of the Holocene in order to reveal warmest and coolest periods as well as rapid temperature changes in the central Asian sector of the subarctic.

The three main sources of information used for this analysis include local chronologies from the central Asian subarctic dendroclimatic network (Fig. 14.11) based on the analysis of living old trees (Briffa et al., 1998; Vaganov et al., 1996); super-long (at least two millennia) tree-ring chronologies constructed from cross-dating the abundant dead wood material of northern Siberia; and subfossil wood material excavated from alluvial deposits in terraces of small rivers in the Taymir and Lower Indigirka regions and even from sites north of the modern tree limit.

The radiocarbon dates of subfossil wood were used to define preliminary calendar time intervals and then the cross-dating method was used to identify absolute dates of tree-ring formation. Unfortunately, not enough material was available to build an absolute chronology for the entire Holocene in Taymir, so the "floating" chronologies (chronologies that cannot be tied with certainty to absolute calendar dates) with numerous radiocarbon dates were also used to analyze past temperature deviations (Naurzbaev et al., 2001).

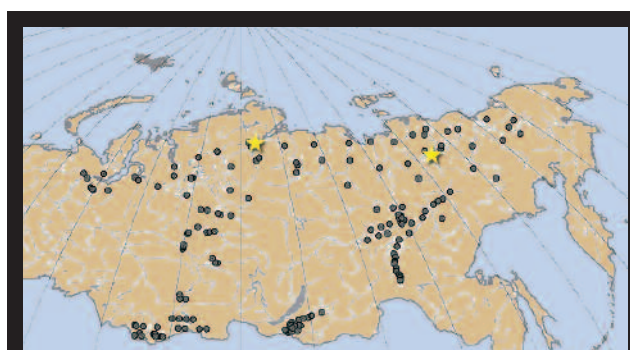
A climatic signal was derived from raw tree-ring measurements using the regional (age) curve standardization


Fig. 14.11. Sites in the dendroclimatic network of the Asian subarctic (circles) and locations of millennial-length chronologies (stars) (Vaganov et al., 1996).

(RCS) approach (Briffa et al., 1996; Esper et al., 2002). This approach is applied to remove the age-dependent variations from single tree-ring series and to retain low-frequency climatic deviations (positive or negative trends) as well as high-frequency variations (year-to-year change) when averaging tree-ring index series. More details about this method of standardization can be found in Briffa et al. (2001), Esper et al. (2002), and Naurzbaev and Vaganov (2000). To verify results, tree-ring chronologies were compared to the instrumental climatic data averaged over a large sector of the subarctic. Finally, the longer-term tree-ring temperature reconstructions were compared to other proxy data including long-term variations in solar radiation (Overpeck et al., 1997), long-term variations in volcanic activity derived from ice-core measurements (Zielinski et al., 1994), and variations in CO_2 concentrations in air trapped in the GISP2 ice core (central Greenland; Wahlen et al., 1991).

14.6.1.1. Climate change in the central Asian subarctic during the last 400 years

Local tree-ring width series for each of 11 sites were obtained by averaging standardized series of individual trees. Between 60 and 70% of the variation in tree-ring width indices in the Eurasian subarctic is caused by changes in summer temperature (Briffa et al., 1998; Vaganov et al., 1996, 1998). A high correlation of local chronologies with temperature (r=0.69 to 0.84) allows the use of simple regression equations for reconstructing temperature based on tree rings. In effect, tree-ring width is used as a simple predictor of summer temperature. In order to avoid an additional procedure of statistical transformation of local tree-ring index series into normalized values of summer temperature variation, each of the local chronologies was normalized to the mean-square deviation in the generalized curve for the Asian subarctic region (Vaganov et al., 1996). To highlight trends and reduce short-term variability, the transformed local series was smoothed with a five-year run-ning mean. Long-term temperature changes dominate the variability of the resulting generalized series. The generalized curve was compared with other temperature reconstructions for the circumpolar Northern Hemisphere (Overpeck et al., 1997) as well as with the main climatic forcing mechanisms.

Temperature variations in the Asian subarctic over the past 400 years correspond well to those observed across the circumpolar north (Fig. 14.12). Both curves clearly illustrate the temperature rise from the beginning of the 19th century to the middle of the 20th century. The main discrepancies between the two curves occur in the second decade of the 19th century and after the 1950s. The correlation of the two reconstructed temperature curves with each other for the preindustrial period is significant, but low (r=0.38, *p*<0.05), and markedly increases (r=0.65, *p*<0.001) for the industrial period (1800–1990) due to a distinct temperature increase that is shown in both curves.

More interesting is the correlation analysis of both curves (Fig. 14.12) with the main climatic forcing factors. The Asian subarctic generalized curve shows a significant correlation with all main climatic forcing factors: with solar radiation (r=0.32 for the entire period and 0.68 for the industrial period from 1800 to 1990); with volcanic activity (r=-0.41 for the entire period and -0.59 for the industrial period); and with atmospheric CO_2 concentration (r=0.65 for the period since 1850). The circumpolar reconstructed temperature curve (Fig. 14.12) is weakly correlated with solar radiation and atmospheric CO_2 concentration, and is not significantly correlated with volcanic activity. This is because more homogenous proxy data (only the tree-ring chronologies) were used for the Asian subarctic reconstruction, while different sources of proxy records (i.e. tree rings, lake sediments, isotopes in ice cores) were used in the circumpolar curve. The correlations with climatic forcing factors further indicate that natural factors (solar irradiance and volcanic activity) explain more of temperature variability that is common to the Asian subarctic and the circumpolar north than does the CO_2 concentration. Spatio-temporal analysis of reconstructed summer temperature variations in the Asian subarctic revealed that recent warming is characterized by an increased frequency of years with anomalously warm summers over the entire Siberian subarctic (the latitudinal dendroclimatic network seen in Fig. 14.11 that is replicated across a distance of 5000 km from east to west; Vaganov et al., 1996).

14.6.1.2. Medieval and current warming in northeastern Eurasia

Millennium length tree-ring chronologies were constructed from samples at two sites close to the northern treeline: east Taymir (71° 00' N, 102° 00' E) and northeast Yakutia (69° 24' N, 148° 25' E). These stands are made up of Gmelin larch (*Larix gmelinii*) and Cajander larch (*L. cajanderi*) in which the oldest living trees are up
Fig. 14.12. Temperature variations from proxy records for the circumpolar Northern Hemisphere (data from Overpeck et al., 1997) and the Asian subarctic (see Fig. 14.11 for locations of sites).
Fig. 14.13. Long-term changes in tree-ring growth in the circumpolar north (data from Esper et al., 2002) and northern Eurasia (combined chronology for east Taymir and northeast Yakutia).

to 1100 years old (Vaganov et al., 2000). Well-preserved dead tree trunks allowed extension of the record farther back than the maximum age of the living samples, allowing the construction of absolutely dated tree-ring chronologies for the periods from 431 BC to AD 1999 (Taymir) and from 359 BC to AD 1998 (Yakutia). The RCS approach was applied to distinguish variation caused by climatic change. These representative tree samples were highly responsive to recorded temperature, allowing the reconstruction of temperatures over the last two millennia with annual resolution. With this long-term record, the instrumental record of 20th-century temperatures can be compared with temperatures during the MWP. Earlier results (Hughes et al., 1999; Vaganov et al., 1996) showed that tree-ring chronologies were highly correlated across distances up to 200 km (up to 500 km in northern regions), so these millennial chronologies represent temperature variations over a large sector of the Siberian subarctic.

The combined chronology for east Taymir and northeast Yakutia was compared with a generalized tree-ring chronology developed for the circumpolar region by Esper et al. (2002; Fig. 14.13). The two chronologies are significantly correlated during last 1200 years (r=0.47, p<0.001), suggesting that they represent long-term temperature trends in the entire Northern Hemisphere subarctic. Both curves show the warming characteristic of the MWP (10th to 13th centuries), decreasing temperature during the Little Ice Age (LIA, 14th to 19th centuries), and a 20th-century temperature increase.

The Siberian summer temperature reconstruction indicates that the warmest centuries were AD 1000 to 1200, with anomalies (from the mean over the last millennium) of 0.70 °C and 0.57 °C for those centuries, and the coolest centuries in were in the LIA period (AD 1600 to 1900), with anomalies for those centuries of -0.42 °C, -0.39 °C and -0.56 °C. The analysis of

long-term trends of summer temperature leads to several conclusions. Present-day warming is estimated to represent an increase in summer temperature of approximately 0.6 °C above the coolest period of the LIA. The reconstruction clearly reveals the timing of the MWP, which occurs in the 10th to 13th centuries. The reconstructed data indicate a greater warming (by about 1.3 °C) above the long-term mean during the MWP compared to the amount of cooling below the mean during the LIA. The results agree well with previous assessments of medieval warming in the Northern Hemisphere (Esper et al., 2002) but show less warming than that projected by climate models or historical analogues that use natural forcing factors such as solar variability and volcanic activity (Budyko and Izrael, 1987).

14.6.1.3. Climate change in the eastern Taymir Peninsula over the past 6000 years

The dendrochronological material discussed in this section was gathered from the Kheta-Khatanga plain region and the Moyero-Kotui plateau in the eastern Taymir Peninsula, near the northernmost present-day limit of tree growth in the world. The wood samples were collected from three areas: the modern treeline in the north forest of Ari-Mas; the modern altitudinal treeline (200–300 m above sea level) in the Kotui River valley; and alluvial deposits in terraces of large tributaries of the Khatanga River (one sample location is 170–180 km north of the modern treeline). The total number of wood samples exceeds 400. The RCS approach was used to standardize individual series (Naurzbaev and Vaganov, 2000). Approximate absolute dating (in contrast to the relative dating developed from the ring series) was established from radiocarbon dates of 45 samples of subfossil wood collected throughout the soil organic layer.

The result of this cross-dating is an absolute tree-ring chronology (see section 14.6.1.2) as well as a series of "floating" chronologies up to 1500 years in length, evenly spaced within the 6000-year interval of the mid- to late Holocene. The relative dating of the "floating" chronologies is based on the calibrated radiocarbon age of the samples (Stuiver and Reimer, 1993).

The resulting curve of the tree-ring index (relative growth) extends over 6000 years, and indicates favorable climatic conditions at about 6000 years BP. This period of warmth represents the latter stages of the postglacial thermal maximum (Lamb, 1977a; section 2.7.4.2). The growth of larch trees at that time surpassed the average radial growth of trees during the last two millennia by 1.5 to 1.6 times. Tree growth (and temperature, accordingly) has generally decreased from the end of the postglacial thermal maximum through the end of the 20th century. Several samples of subfossil wood collected in the flood plain of the Balakhnya River were accurately dated in accordance with the "floating" chronology to the period from 4140 to 2700 BC. Due to the geography of the watershed, these samples could not have originated from the more

southern regions, which means that during the post-glacial thermal maximum the northern treeline was situated at least 150 km further north than at present. The postglacial thermal maximum can also be clearly identified by the relative levels of the stable isotope carbon-13 (^{13}C) in the annual tree rings (Naurzbaev et al., 2001). Increased ^{13}C concentration in annual layers of wood of this species (Cajander larch) is highly correlated with warm summer temperatures. High ^{13}C content is found in wood dated to the period that ring-width techniques reconstruct as warm, confirming high temperatures during this period.

Quantitative evaluation of mean deviations of average summer and annual temperatures demonstrates higher temperature variability during the postglacial thermal maximum compared to the 3.5 ºC variability typical of the 20th-century instrumental temperature record. This corresponds well to the earlier published data (Naurzbaev and Vaganov, 2000) and to findings of subfossil wood in alluvial deposits of the Balakhnya River 150 km north of the present-day treeline. Reliable dates for the postglacial thermal maximum, in agreement with the "floating" chronologies, indicate that during this period sparse larch forest extended at least 1 to 1.5 degrees of latitude further north than the northernmost present-day forest limits in the Ari-Mas massif.

A comparison of the long-term temperature reconstruction for the Taymir Peninsula with other indicators of long-term temperature change in the high latitudes of the Northern Hemisphere during the Holocene (including summer melting on the Agassiz Ice Cap, northern Ellesmere Island, Canada; summer temperature anomalies estimated from the elevation of carbon-14 dated subfossil pine wood samples in the Scandes mountains, central Sweden; and temperature reconstruction from oxygen isotopes in calcite sampled along the growth axis of a stalagmite from a cave at Mo i Rana, northern Norway; Bradley, 2000) reveals several noteworthy features. During much of the Holocene, and especially starting between 9000 and 8000 years BP, the overall high-latitude Northern Hemisphere temperature steadily decreased, although there were shorter fluctuations with significant amplitude. This distinct trend of general temperature decrease agrees with the Taymir chronology. The concurrence of characteristic temperature fluctuations can be seen, for example, in significant decreases at about 6000 years BP and 4000 years BP, and increases at about 3000 years BP and 1000 years BP (the MWP). This coincidence suggests that some regions of the Arctic experienced long-term temperature changes in common with the high-latitude mean, which has been reconstructed using various proxy data. These interpretations of the data are supported, for instance, by the results of radiocarbon and dendrochronological dating of wood remains from the MWP collected north of the modern treeline in the Polar Urals (Shiyatov, 1993; section 14.11.1.3). However, some aspects of a reconstruction that infers higher summer temperatures dur-

ing the postglacial thermal maximum than have been recorded in the late 20th century remain uncertain and subject to confirmation from additional research. The range in estimates obtained from different sources of the degree to which reconstructed temperature at its postglacial maximum exceeded the maximum warmth of the 20th or early 21st centuries is significant: from 0.6 ºC (glacier and stalagmite layers and bottom deposits) to 3 to 3.5 ºC (indicated by Taymir tree-ring chronology and the greatest extension of forest in the Scandinavian mountains; Kullman and Kjallgren, 2000). These deviations in reconstructed temperature may have been influenced by local conditions, different sensitivities of proxy sources to temperature change, or inadequate calibration models. Unfortunately, at present it is impossible to determine the cause of these deviations.

To detect the anthropogenic component of climate variations at high latitudes it is important to know whether temperature is *already* affected by increasing GHG concentrations and whether the rate of temperature increase is unprecedented in the period of instrument-based temperature records. A series of synthesizing studies, as well as simulations with GCMs, have established that anthropogenic emissions have had a significant influence on the rate of temperature rise in the Northern Hemisphere (Mann M. et al., 1998). However, in contrast to global trends, in the long-term northern Siberia tree-ring chronologies the present high-latitude summer temperature increase is less than that experienced during the postglacial thermal maximum. In this region, natural climatic forcing factors appear to have been more significant than the combination of human and natural factors producing the current summer warming thus far. In the Siberian study area, the amplitude of the current summer warming is not thus far greater than the warming during the MWP. This may be partly explained by the difference between regional and global trends, and partly by the difference between the trends in summer and annual temperature.

To determine with confidence whether the *rate* of temperature increase is unprecedented, it is necessary to obtain good quantitative data with high temporal resolution for the Holocene that will help to identify periods of drastic natural temperature increases in the past, and then to examine the amplitude of such drastic increases to see if there are natural limits during such periods of change. Therefore, one of the urgent tasks at present is the construction and analysis of super-long-term tree-ring chronologies for Eurasia with an adequate amount of subfossil wood. Such studies are being intensively conducted in Europe (Baillie, 2000; Leuschner and Delorme, 1988; Leuschner et al., 2000) and in north Asia (Hantemirov, 1999; Shiyatov, 1986; Vaganov et al., 1998). They should soon provide high-resolution tree-ring chronologies for Eurasia that can be used for quantitative reconstruction of temperature and for calibration of data obtained from other indirect sources of climatic information with lower temporal resolution.
Fig. 14.14. Annual temperature anomaly (from 1671–1973 average) reconstructed from white spruce at the North American treeline (see D'Arrigo et al. (1996, 2001) and Jacoby and D'Arrigo (1989) for details of the reconstruction technique).

14.6.2. Past climate change in Alaska and Canada

One of the first large-scale climate reconstructions based on boreal tree-ring data was a study of treeline white spruce across northern North America (primarily Canada) covering about 90 degrees of longitude or about one-third of the circumpolar northern treeline extent (Jacoby and D'Arrigo, 1989). This chronology was based on the positive response of tree growth at treeline to temperature, and allows the reconstruction of mean annual temperature anomalies back to AD 1700 (Fig. 14.14). Key features of the reconstruction are intermediate temperatures during most of the 18th century, sharp cooling during the first half of the 19th century, gradual warming from the mid-19th century to a mid-20th century peak, and a slight cooling from about 1950 to the 1970s. If recent proxy data or climate records are available in a given locality to compare to the overall long-term record, unusual warming during the last decades of the 20th century is often noted (Jacoby and D'Arrigo, 1989; Jacoby et al., 1988). Some of the recent increase in annual temperatures in this reconstruction can be attributed to recovery from the last stages of the LIA.

Since the studies of the late 1980s, other analyses have added more spatial representation and longer temporal coverage (e.g., Mann M. et al., 1999) leading to an essentially complete coverage of the 20th century (Esper et al., 2002). The most recent reconstructed annual temperature curves confirm the major anomalies in annual temperature of the North American treeline curve of Jacoby and D'Arrigo (1989; see Fig. 14.14) that has served as the basis for standard Arctic temperature reconstructions (e.g., Overpeck et al. 1997).

The need to splice tree-ring records from overlapping generations of trees introduces some questions about whether the successively earlier generations of tree-ring records have been calibrated correctly and adequately preserve low-frequency variations (longer-term trends) in temperature. Methods of processing tree-ring data to preserve the low-frequency variations correctly have improved, allowing such trends and their possible causes to be identified (Esper et al., 2002). The Esper et al. (2002) reconstruction shows more prominent low-frequency trends, including the MWP and the LIA, than previous reconstructions or global or Northern Hemisphere-wide averages.

New technology, such as x-ray density (Jacoby et al., 1988) and stable isotope techniques, allow measurements of tree-ring properties in addition to ring width. Maximum latewood density of northern conifers increases when mid- to late growing season moisture stress is great (D'Arrigo et al., 1992). Maximum latewood density of boreal conifers also may represent an index of canopy growth where productivity is temperature-related, as indicated by satellite-sensed normalized difference of vegetation index (NDVI; representing "greenness" of the land surface) values (D'Arrigo et al., 2000). Carbon-13 isotope content is generally measured as "discrimination", which represents the difference in the amount of the isotope in sampled plant tissue compared to a reference standard. Less ^{13}C discrimination (greater ^{13}C content in sample) indicates production of the sampled plant tissue under a condition of restricted stomatal exchange, generally as a result of moisture stress (Livingston and Spittlehouse, 1996).

Maximum latewood density, ^{13}C isotope discrimination, and ring width of upland white spruce stands in central Alaska are well correlated with each other (Barber et al., 2000). Latewood density and ^{13}C isotope discrimination contain information specific to the climatic conditions of the year of ring formation, in contrast to ring width (which is influenced by two or more years of temperature), making them ideal for reconstructing past climates (Barber et al., 2000). No continuous instrument-based
Fig. 14.15. Warm-season (Apr–Aug) temperature regimes and regime shifts in central Alaska from 1800 to 1996 from observations and reconstructed from tree-ring density and ^{13}C isotope discrimination (Barber et al., 2000; Juday et al., 2003).

temperature records exist for the western North American boreal region until the early years of the 20th century, and few records exist until the mid-20th century.

A 200-year reconstruction of warm-season (April to August) temperature at Fairbanks, Alaska, based on tree-ring density and ^{13}C isotope discrimination has been constructed (Barber et al., 2004; Juday et al., 2003; Fig. 14.15). The warm-season temperature reconstruction for Interior Alaska has been divided into multi-decade segments or warm-season temperature regimes. Regimes represent multi-decadal periods of characteristic temperatures that persist between periods of rapid climate change (Fig. 14.15). Note that the first half of the 20th century experienced extended periods of cool summers, which relieved moisture stress of low-elevation white spruce. The reconstruction of warm temperatures in the mid-19th century is out of phase with overall Northern Hemisphere means, but is strongly established by the proxies (^{13}C isotope discrimination and maximum latewood density) used in the reconstruction. A reconstruction of the annual Pacific Decadal Oscillation (section 2.2.2.2) index using western North American tree-ring records, accounting for up to 53% of the variance in instrumental records and extending back to 1700, also indicates that decadal-scale climatic shifts occurred in the northeast Pacific region prior to the period of instrumental record (D'Arrigo et al., 2001). These results suggest that rapid temperature shifts followed by semi-stable periods are a fundamental feature of climate change in that region.

From the perspective of two centuries, the recent very high rate of temperature increase in the second half of the 20th century in Interior Alaska is partially explained by a change from some of the lowest warm-season temperatures to some of the highest in the entire period (Fig. 14.15). Unlike the annual temperature reconstruction based on North America-wide treeline white spruce (Fig. 14.14), the Interior Alaska reconstruction (Fig. 14.15) indicates that the mid-19th century (Regimes 19.2A and 19.2C) was one of the warmest periods and the mid-20th century was a period of unusually cool summers. Because many of the climate records available in this part of the world begin only in the late 1940s or early 1950s (during the one of the coldest periods of the 20th century) and continue to the present (the warmest period of the last millennium), the instrument-based record indicates a higher rate of temperature increase than the longer-term reconstructions that incorporate several cycles of temperature increases and decreases. This suggests that the strong late 20th-century warming (during the warm season) in western North America may have a considerable component of natural climate variability in the signal.

There are still regions of the north that are not represented in large-scale temperature reconstructions, especially on the timescale of the past millennium. Recorded data and climate models strongly indicate that there are very likely to be important regional differences in temperature trends across the high-latitude north. In fact, a comparison of the large-scale reconstruction of northern North American annual temperature anomalies with the Interior Alaska reconstruction shows opposite trends (Fig. 14.2) that appear to be a consistent part of the climate system.

Across the Northern Hemisphere and beginning in different regions at different times, northern treeline trees display a reduced sensitivity to growing-season warmth (Briffa et al., 1998; Jacoby and D'Arrigo, 1995; Vaganov et al., 1999). The reduction in the positive response of some trees to warm-season temperature seems to have occurred around 1970, when warming resumed after a cool interval in the mid-20th century. When late 20th-century warming resumed, some trees continued to increase in radial growth in response to the warmer conditions. However the growth increase per unit of temperature increase was not nearly as great as previously, and in some trees temperature no longer had a reliable predictive relationship to tree growth at all (Briffa et al., 1998). In Alaska, much of the change can be attributed to greater moisture deficits associated with higher warm-season temperatures (Jacoby and D'Arrigo, 1995). In northern Siberia, the effect is attributed to shorter periods of thawed soil because of increased depth of snow cover, an indirect effect of warmer winters (Vaganov et al., 1999). For other areas, there are hypotheses about air pollution, UV radiation damage, and other factors (Briffa et al., 1998).

14.6.3. Past climate change in northwestern Europe

In the past few decades, Scandinavian tree-ring data have provided an increasing amount of information about past climate variability. Natural reserves preserve a number of old and mature forests virtually untouched by humans, especially in central and northern Scandinavia. Scots pine growing close to altitudinal or latitudinal distribution limits in the Scandinavian Mountains or in northernmost Sweden mainly respond to summer temperatures (with increased growth) and data from such sites have been used to interpret past climate variability (Briffa et al., 1990; Grudd et al., 2002; Gunnarson B. and Linderholm, 2002; Linderholm, 2002). Furthermore, due to the proximity to the Norwegian Sea, and hence the influence of maritime air masses brought in with westerly and south-westerly winds, precipitation may be a growth-limiting factor in moist areas, such as the western slopes of the Scandinavian Mountains or in peatlands (Linderholm et al., 2002, 2003; Solberg et al., 2002). High-frequency North Atlantic Oscillation signals (section 2.2.2.1) have been found in tree-ring data from east-central Scandinavia (Lindholm et al., 2001).

The relationship of climate to tree-ring variability in Scots pine in Scandinavia has been studied in a wide range of growth environments. A comprehensive study was made of pine growing on peatlands along a north–

south profile through Sweden to see if the trees contained high-resolution climate information (Linderholm et al., 2002). Peatland pines were also compared to pines growing on dry sites. Pines growing on peatlands are dependent on growing-season temperature and precipitation, as well as on local water-table variations, which are influenced by longer-term trends in both temperature and precipitation. There is a lag of up to several decades in the response of the pines to water levels, such that trees are integrating the immediate effects of growing-season climate as well as a delayed effect from the water table, making them unsuitable for high-frequency climate reconstruction. The sensitivity of pines growing on peatland also changes depending on climate. When the growing season is wet and cold, temperature is more important and trees respond positively to temperature, in particular to July temperature. Precipitation response increases to the south but is never as important as for pines growing on dry soils. Precipitation is important mainly in controlling water-table levels (Linderholm et al., 2002).

A 1091-year record of tree growth from AD 909 to 1998, developed from living and subfossil Scots pine in the central Scandinavian Mountains, provides evidence of low-frequency climate variation (Gunnarson B. and Linderholm, 2002). July temperatures had the largest effect on the growth of these trees, but growth was also positively and significantly correlated with October to December temperatures in the previous year. The response to precipitation during the vegetative period was negative although not significantly. The authors inferred that the chronology represents summer temperatures for the central Scandinavian Mountains, although it is suggested that care should be taken when interpreting the record. The chronology indicates prolonged excursions below the mean (cool conditions unfavorable for tree growth) in the mid-12th and the 13th centuries, and in the mid-16th and late 17th centuries (corresponding to the early and late LIA, respectively). Below-mean conditions in the late 18th century correlate with a "recent cold period" (Fisher et al., 1998; Grove, 1988; Jones and Bradley, 1992; Lamb 1977b). The chronology also provides evidence for the MWP in the 10th and early part of the 11th centuries as well as warmer periods during the mid-14th, mid-17th, and 20th centuries (Gunnarson B. and Linderholm, 2002).

14.7. Direct climate effects on tree growth

14.7.1. The Flakaliden direct warming experiment

14.7.1.1. Background

In 1994, a soil warming experiment began at Flakaliden near Vindeln, 65 km northwest of Umeå, Sweden (64° 07' N, 19° 27' E). The experiment is in a planted Norway spruce forest established in 1963. The environment of the area is representative of the northern portion of the European boreal forest. Mean annual temperature is

2.3 ℃ and mean annual precipitation about 590 mm. The goals of the Flakaliden warming experiment are to:

- quantify the effect of soil warming on the seasonal course of plant respiration and phenology of trees at low (irrigated) and high (irrigated and fertilized) availability of soil nutrients;
- test and improve available mechanistic models used to project impacts of climate change on respiratory dynamics in plants and forest soils; and
- to estimate net carbon budgets for boreal Norway spruce at the tree, stand, and regional scale, in present and future climates.

The soil warming treatment was installed in late 1994 in the buffer zone of one irrigated and one irrigated and fertilized stand; air temperature was not directly modified. Each heated subplot has a corresponding unheated control plot. The reason for using treatments including irrigation was to reduce the risk of drying the soil as an effect of the soil warming. The experiment was not designed to produce the effects of climate warming *per se*, but to isolate the effect of one of the most distinctive features of the boreal forest that is thought to contribute to its great carbon storage – soil temperature. While aboveground production of plant material is relatively great in boreal forests, cold soils limit the rate of decomposition that releases the fixed carbon back into the atmosphere. Therefore, soil warming, if it were to increase decomposition of stored soil carbon more than it affected production, could have a disproportionate effect on carbon balance.

In the Flakaliden experiment, soil warming starts in April each year, about five weeks before the soil thaws in the unheated plots. The soil temperature is increased by 1 ℃ per week, until a 5 ℃ difference between heated and control plots is reached. In late autumn, when the soil temperature in the control plots approaches 0 ℃, the soil temperature of the heated plot is decreased by 1 ℃ per week. If the control plots do not freeze before 1 November, the temperature reduction is still initiated (CarbonSweden, 2003).

14.7.1.2. Questions, hypotheses, and results

Based on the assumptions of doubled atmospheric CO_2 concentration and a 4 to 6 ℃ increase in annual mean temperature, the following responses were hypothesized:

- Increased CO_2 and temperature will have a small positive effect on biomass production in boreal forest growing on nutrient-poor sites. The stimulating effect will mainly be due to a shorter period with frozen soils and increased nitrogen mineralization.
- Increased CO_2 and temperature will have a positive effect on photosynthesis in boreal forest growing on sites with good nutrient availability. The net effect on biomass production will, however, be reduced as an effect of increased plant respiration (mainly foliage).

- In boreal forests growing on poor sites, an increase in temperatures will stimulate soil respiration more than biomass production and therefore the net carbon balance will be negative until a new equilibrium is reached. The strength of the carbon source will depend on site index and the size of the soil carbon pool.
- The boreal forest ecosystems will be a major sink for atmospheric carbon, once new equilibriums between carbon fixation and decomposition of soil organic matter have been reached. The time to reach a new equilibrium will depend on site index and the size of the soil carbon pool.

Soil moisture is not normally limiting to growth at Flakaliden (Bergh et al., 1999). The earlier spring soil thawing and later autumn freezing in heated plots increased mineralization of soil organic matter, which increased the concentration of most nutrients in the needles (Bergh and Linder, 1999). The effect was most pronounced during the first years of warming, but was still apparent after the fourth season, by which time stem-wood production had increased by approximately 50% compared to the control plots (Jarvis and Linder, 2000). Earlier access to water in spring results in an earlier start of photosynthesis (Bergh and Linder, 1999). After six seasons of warming at Flakaliden, stem volume production (m^3/ha/yr) was 115% higher on heated and irrigated plots than on unheated control plots; on heated, irrigated, and fertilized plots production was 57% higher than on unheated plots. The results indicate that in a future warmer climate, with increased nitrogen availability and a longer growing season, biomass production is very likely to increase substantially on both low- and high-fertility sites in the more humid parts of the boreal forest (Strömgren and Linder, 2002). However, the Flakaliden results are specific to soil warming without air-temperature change incorporated and it is too early to determine whether the observed responses are transitory or will be long-lasting.

In recent years, the large contribution of fine root turnover (growth and death within the growing season) as a factor in the annual production and storage of carbon in boreal forests has been recognized. Interactive effects of soil warming and fertilization on root production, mortality, and longevity at Flakaliden demonstrated that that nitrogen addition combined with warmer soil temperatures decreases the risk of root mortality, and annual fine root production is a function of the length of the growing season (Majdi and Öhrvik, 2004). Under scenarios of climate change that increase soil temperature, and maintain adequate soil moisture and sufficient nitrogen, root production (and carbon stored in roots at a given time) in boreal forests is very likely to increase, especially at low-fertility sites.

The influence of soil temperature on boreal forest growth and carbon storage in natural field situations does not appear to be as great as the potential demonstrated in the Flakaliden results. After four years of warming, a major temperature acclimation had occurred and there was only a small difference in soil CO_2 flux between heated and non-heated plots (Jarvis, 2000). The timing of soil thawing (date of near-surface soil temperature rapidly increasing above 0 ºC) was not a good predictor for the start of spring photosynthesis in boreal coniferous forest at five field stations in northern and southern Finland, northern and southern Sweden, and central Siberia. The best predictor of the start of spring photosynthesis was air temperature (Tanja et al., 2003). In one case, photosynthesis commenced 1.5 months before soil thawing. At most sites a threshold value for air-temperature indices projected the beginning of photosynthesis in the spring, which varied among the sites by 30 to 60 days. The threshold values varied from site to site, probably reflecting genetic differences among the species and/or differences in the physiological state of trees in late winter and early spring induced by climate. A single physiological temperature threshold for the start of photosynthesis may not exist.

14.7.2. Climate effects on tree growth along the Central Siberia IGBP transect

The International Geosphere-Biosphere Programme (IGBP) is an international, interdisciplinary scientific research program built on networking and integration. It addresses scientific questions requiring an international approach, and undertakes analysis, synthesis, and integration activities on broad earth-system themes. The goals of the IGBP are to develop common frameworks for collaborative research, form research networks, promote standardized methodologies, facilitate construction of global databases, undertake model and data comparisons, and facilitate efficient patterns of resource allocation.

In the early 1990s, the IGBP developed the Global Change and Terrestrial Ecosystems project to establish terrestrial transects for global change research as one way to study ecosystem and climate change across large spatial scales (Canadell et al., 2002). The IGBP terrestrial transects run for more than 1000 km along specific environmental gradients such as temperature or precipitation, and along more conceptual gradients of land-use intensity. They often cross ecotones such as tundra–taiga that are believed to be highly sensitive regions with strong feedbacks to global change. The Central Siberia IGBP transect was one of five high-latitude IGBP transects.

14.7.2.1. Climate response functions of trees along a latitudinal gradient

The geography of central Eurasia offers an excellent opportunity to examine how climate influences tree growth along an uninterrupted transect from the cold tundra margin in the north to the semi-arid steppe grassland of central Asia. This transect approach can provide some ideas about how climate change might affect growth by comparing the climate factors that his-

torically and currently control tree growth as one proceeds southward. However, several limitations to this approach should be considered. For example, the genetics of individual trees of even the same species change from north to south. However, the comprehensive view of how tree growth responds differently to climate from cool to warm regions is still quite useful.

To define the main climatic factors that influence tree-ring growth in various regions along the Central Siberia IGBP transect, correlation coefficients of tree-ring structure chronologies with monthly temperature and precipitation were calculated (Fritts, 1976; Schweingruber, 1988, 1996). Tree-ring data from Siberian larch, Gmelin larch, Siberian spruce (*Picea obovata*), and Scots pine from 46 sites located in regions from the forest–steppe zone in the south to the forest–tundra zone in the north were used (Fig. 14.16). The relationship of tree-ring width to climate was investigated at all sites.

To strengthen the climatic signal common to each region, tree-ring data from sites were averaged as regional chronologies when sufficiently high correlation of master chronologies from the same vegetation zone permitted. Averaged regional chronologies were obtained for the following vegetation zones along the transect: forest–tundra and the northern part of the northern taiga; northern taiga; middle taiga; and southern taiga. These chronologies were compared to regional climatic data averaged for several meteorological stations. In the south, in the forest–steppe zone, the similarity of master chronologies was lower and three regional chronologies were obtained. They were correlated with the data from the nearest meteorological stations.

Comparison of the climatic response functions obtained for trees growing at different regions along the transect show that there is a change in the climatic factor that

defines tree-ring growth at sites located along the temperature gradient in central Eurasia (Fig. 14.17). Summer temperature is one of the most important external factors that define tree-ring growth at the northern treeline (Vaganov et al., 1996, 1999). It positively influences tracheid production and explains up to 70% of the variability in tree-ring width. In the middle taiga region, the effect of summer temperature on tree-ring growth decreases and the influence of precipitation increases (Kirdyanov, 2000). In this region, winter precipitation has a strong negative effect on tree-ring growth, while June temperature has a positive influence. In the forest–steppe zone, tree-ring climatic response functions are typical of regions with limited moisture (Fritts, 1976), where variability in tree-ring width is mainly explained by moisture variability (directly influenced by precipitation and indirectly influenced by temperature). The negative influence of spring and early summer temperature is explained by water loss from the soil at the beginning of growing season. High temperatures in the previous August and September affect soil water content, which is important for tree-ring growth activation during the next growing season (Magda and Zelenova, 2002; Schweingruber, 1996).

From north to south along the transect, the limiting positive effect of summer temperature in the forest–tundra zone is replaced by the limiting effect of spring precipitation (positive) and early summer temperature (negative) in the forest–steppe zone (Fig. 14.17). Climate conditions (soil moisture and temperature) at the beginning of and during the first part of the growing season play the key role in determining annual radial tree growth and wood production at various latitudes from the northern treeline to the forest–steppe zone. Moving from north to south, the start of the tree-ring growth season shifts to earlier dates. June and July conditions are important for trees growing at the northern treeline, whereas April through June precipitation and temperature influence tree-ring formation in the forest–steppe zone (Fig. 14.17).

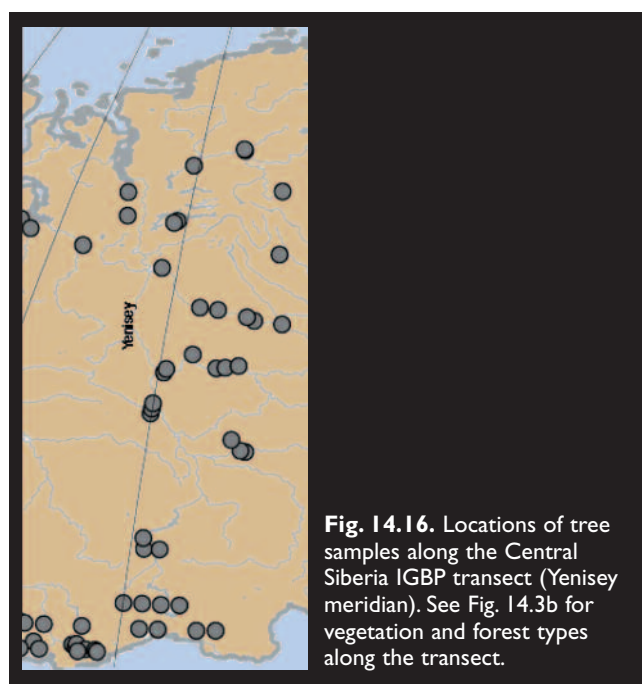
Under climate scenarios projected by the ACIA-designated models, trees currently growing in a given central Eurasian forest zone begin to experience temperatures near the end of the 21st century that are typical today of the next zone to the south. The simplest response (linear) would be for the propagules of the vegetation of any zone under consideration to migrate northward and eventually reconstitute the zone further north – in effect a "migration" of the zone northward through regeneration over time, so that present-day zones are replaced in the same sequence by the zones found to the south (Fig. 14.17). However, novel features of the ACIA-designated climate projections and their effects through time could bring about a nonlinear forest response (Fig. 14.17). It is difficult to make specific projections of these outcomes, but it is possible that some processes resulting from the ACIA-designated climate projections will produce unique effects not seen within the range of temperature variability experienced during the last millennium.


Fig. 14.16. Locations of tree samples along the Central Siberia IGBP transect (Yenisey meridian). See Fig. 14.3b for vegetation and forest types along the transect.
Fig. 14.17. Statistically significant correlations between tree-ring increments and climatic variables (typical climatic response functions) for different vegetation zones of central Eurasia along the Central Siberia IGBP transect. Potential alternative outcomes of climate change are also depicted. A warmer climate could result in the replacement of existing forest vegetation zones in sequence (linear response) or novel ecosystems could appear (nonlinear response) (data from Panyushkina et al., 1997; Vaganov, 1989; Vaganov et al., 1985, 1996).

For example, all the ACIA-designated models project an increase in temperature that is very likely to result in thawing of permafrost along the southern limit of its present-day distribution (section 6.6.1.3) and in low-elevation basins in the southern Yukon, central Alaska, and southwestern portions of the Northwest Territories. Permafrost thawing would transform forest soils and create site conditions that have few or no current analogues. The ACIA-designated models project annual temperatures in the southern boreal forest of central Eurasia at the end of the 21st century that are typical of present-day temperate forest, but the actual amount of moisture supply and species migration could either permit or hinder development of temperate forest in this region. The current territory of southern taiga is projected to be replaced by forest–steppe (Tchebakova et al., 1995) with a 15% phytomass decrease (Monserud et al., 1996) in a warmer climate, and forest degradation and decline during the transition period are very likely to result in a major increase in forest debris and forest flammability. The difference between the ACIA-designated model projecting the largest increase in central Eurasian growing season temperature, generally the CGCM2, and the model projecting the smallest increase, the CSM_1.4, was generally between 15 and 20%. At the extreme upper range of temperature increases in the CGCM2 and the ECHAM4/OPYC3 scenarios, it is possible that warming and drying effects will bring tundra into contact with semi-arid steppe (Fig. 14.17). Empirical relationships between evapotranspiration and vegetation in central North America project that aspen parkland will extend into the Arctic (Fig. 14.1, Hogg and Hurdle, 1995) under a scenario based on doubled atmospheric CO_2 concentrations.

14.7.2.2. Variability in the strength of climate influence on tree growth

Tree-ring variability in Gmelin larch, Siberian larch, and Scots pine was compared from sites located at different latitudes along the Central Siberian IGBP transect. Tree-ring width chronologies were calculated for trees from the forest–tundra zone (71° N); northern (64°–69° N), central (61° N), and southern (58° N) taiga regions; the forest–steppe zone (53° N); and high-elevation forest (51° N) (Table 14.6). To obtain comparable values of mean tree-ring width for different regions, only growth of mature trees (i.e., the period when the age trend in individual tree-ring width curves is not pronounced) was analyzed. The average age of larch trees growing in the south of the study area is less than that of northern larches. Hence, mean tree-ring width for larch from the north (61°–71° N) was calculated for the most recent 50 years for trees older than 200 years, and at the sites located at 57° to 51° N, for larch after 150 years of growth. Because pine trees are generally younger than larch growing at the same latitude, mean tree-ring width of pine was calculated for the most recent 50 years for trees older than 150 years.

Correlation coefficients of individual chronologies with the master time series and coefficients of sensitivity indi-

cate the strength of environmental influences that syn-
chronize tree-ring growth at the same site. The higher
these two parameters, the greater the role of the envi-
ronment in tree-ring growth. These statistics were aver-
aged for the master chronologies obtained for sites from
the same latitudinal belt.

Tree-ring width in larch trees increases from north to
south up to the region of southern taiga (57° N; Table
14.6), then decreases in the high-elevation forest zone of
Tuva (51° N). Correlation of individual chronologies
with master time series and tree-ring sensitivity values
indicate a decrease in environmental influence on tree-
ring growth from north to south along the transect.
The highest correlation coefficients were obtained for
the northern treeline region and sites 200 km to the
south, while the lowest were in the southern taiga
region. Tree growth in the southern taiga region is less
sensitive to environmental influences than growth of
northern trees and trees at high elevations (Table 14.6).
Similar changes in tree-ring variability along the transect
were found for pine. Tree-ring width increases from the
northern border of the pine area to the south taiga
region. At the same time, the correlation of individual
series with the master chronology and the sensitivity
both decrease (Table 14.6). By contrast, in the forest–
steppe zone (53° N) the year-to-year variability in pine
growth is more closely synchronized to various local cli-
mate factors rather than an overall regional signal.

These trends in tree-ring width variability along the
north–south Central Siberian IGBP transects repeated
longitudinally are typical of tree growth in the entire
Siberian boreal zone. Shashkin and Vaganov (2000)
reported similar results (increasing larch tree-ring width
with decreasing site latitude) from Yakutia, East Siberia,
caused by the gradient of environmental factors that

most influence tree-ring growth. At the northern tree-
line, lack of summer warmth is the main climatic factor
that limits ring growth (Kirdyanov and Zarharjewski,
1996; Vaganov et al., 1996). As a result, at such high lati-
tudes, large-scale patterns of summer temperature syn-
chronize the growth of trees not only at the same site
but also at sites located up to 800 km apart (Vaganov et
al., 1999). Temperature increases projected by the ACIA-
designated models are very likely to have positive effects
on larch growth across this area.

The influence of summer temperature decreases moving
southward from the northern end of the transect.
This gradient of environmental control leads to the
higher growth rate and lower sensitivity of tree growth
to climate in the middle of the transect. However,
toward the southern portion of the transect, there is
once again an increase in the correlation between indi-
vidual tree-ring growth and sensitivity of master
chronologies. Summer warmth in these dry regions is a
strongly unfavorable factor for pine ring formation at its
southern limit of distribution and larch at its lower ele-
vation limit. Therefore, at the southern end of the tran-
sect, the strong influence of environmental factors on
larch growth in high-elevation forest and on pine in the
forest–steppe zone synchronize ring formation in trees
on similar types of sites. The broadly shared environ-
mental controls caused better registration of environ-
mental changes in tree-ring structure (higher sensitivi-
ty) among sites. Temperature increases projected by the
ACIA-designated models are very likely to have negative
effects on larch and pine growth across the southern
part of the transect.

Table 14.6. Statistical characteristics of larch and pine ring-
width chronologies from different locations along the Central
Siberia IGBP transect.

Latitude (° N)	Number of sites	Number of trees	Mean tree-ring width (mm)	Correlation with master chronology	Coefficient of sensitivity
Larch

[a]Two samples at this latitude; the number of trees is the total for both sites.

Fig. 14.18. Historic and reconstructed relationship between
white spruce growth and summer temperature at Fairbanks,
Alaska, and projections based on climate scenarios. The tree
growth sample includes 10 stands across central Alaska. Summer
temperature is an excellent predictor of white spruce growth.
Because higher temperatures are associated with reduced
growth and growth is the dependent variable, the temperature
scale (left axis) has been inverted. Given the historical relation-
ship between the variables and the scaling of these axes, the
temperatures projected by the ACIA-designated models can be
used to infer the approximate level of growth (right axis) possi-
ble in the future (data from Barber et al., 2004).

14.7.3. Response of high-latitude conifers to climate and climate change scenarios

14.7.3.1. White spruce in Alaska and Canada

The scientific literature on the relationship of tree-ring width to climate in northern North America is dominated by studies of white spruce carefully selected in order to allow the reconstruction of past climates (section 14.6.2) from trees that achieve greater growth with warmer temperatures and lower growth with cooler temperatures. However, radial growth of white spruce on upland sites across a broad area of central Alaska exhibits a strong negative response to summer temperature (Juday et al., 1998, 1999; Fig. 14.18). The negative relationship of radial growth to summer temperature is consistent throughout the 20th century, and occurs in a broad range of dominant and co-dominant trees in mature and old stands (Barber et al., 2000). The growth of white spruce on these sites is best projected by the mean of May through August temperature in the year of ring growth and the year prior (Barber et al., 2000). This relationship between climate and tree growth is sustained during the period of the instrumental record as well as the period for which summer temperatures were reconstructed from ^{13}C isotope content and latewood density.

Based on this strong relationship, the two-year mean of May through August temperature for the Fairbanks grid cell was calculated from the ACIA-designated model and used to project future growth of this species on similar sites (Fig. 14.18). Because the relationship between temperature and growth is negative (less growth in warmer conditions) and the response variable of interest is tree growth, the temperature axis is inverted (increasing temperature downward) in Fig. 14.18.
Fig. 14.19. Historic relationship between white spruce growth and mean warm-season temperature (June, July, and September of the growth year and April of the previous year, smoothed with a 5-year running mean), and climate scenarios for central and northern Labrador, Canada (data from D'Arrigo et al., 1996).

The CGCM2 scenario projects the highest temperatures for the Fairbanks grid cell, although with a reduced range of annual variability. The CSM_1.4 scenario projects the least warming in the grid cell of the five ACIA-designated models, with variability similar to the recorded data (Fig. 14.18). If white spruce growth maintains the same relationship to temperature in the scenario period as during the calibration period, under the CGCM2 scenario growth is very likely to cease (the empirical relationship reaches zero growth) by the end of the scenario period (Fig. 14.18). Under the CSM_1.4 scenario, white spruce growth is very likely to decline to about 20% of the long-term mean. The zone of temperature and tree growth in Fig. 14.18 that corresponds to 20% or less of long-term mean growth has been highlighted as a "zone of probable species elimination". The stressed condition of trees in such a climate is likely to predispose them to other agents of tree mortality such as insect outbreaks (section 14.8) and diseases. While the CSM_1.4 scenario does not produce warming by the end of the scenario period that is empirically associated with zero growth, this white spruce population would be growing in a climate that is very likely to greatly reduce its growth. This climate and reduced level of growth almost certainly would place the trees that occur there now at an elevated risk of mortality, primarily from fire (section 14.9.2.3) and insects (section 14.8.2). White spruce in this region that demonstrate this climatic response are among the largest, most rapidly growing, and commercially valuable in boreal Alaska.

At high latitudes and altitudes where moisture is not limiting, white spruce has a positive growth response to summer temperature. The growth of near-treeline white spruce north of Goose Bay, Labrador in eastern Canada is positively correlated with the mean of monthly temperature in June, July, and September of the growth year and April of the previous year (Fig. 14.19; D'Arrigo et al., 1996). Some of the trees in the sample may have been responding to non-climatic factors in the early 1950s and especially in the late 1990s when a significant short-term growth decline occurred (Fig. 14.19). The long-term tree-ring chronology available from the Labrador near-treeline sample reconstructs past climates in general agreement with those of several instrument-based and modeling studies of this sector of the North Atlantic (D'Arrigo et al., 1996).

If the relationship between temperature and tree growth in the Labrador sample is maintained in the future, the ACIA-designated model projections again provide a basis for evaluating possible tree growth responses. In the grid cell containing Goose Bay, the CSM_1.4 model projects the greatest amount of warming by the end of the scenario period and the GFDL-R30_c scenario projects the least warming. The long-term mean of ring-width growth in the sample is set to 1.0 and the variation is expressed in units of standard deviation (Fig. 14.19). As projected using the regression lines of the scenarios, the growth of trees that retained the historical relationship of temperature and growth

would increase to about 0.3 standard deviations greater than the long-term mean under the GFDL-R30_c scenario and nearly 0.5 standard deviations greater under the CSM_1.4 scenario. Both scenarios produce warming and inferred levels of tree growth that this area has not experienced since the beginning of the proxy record in the late 1400s. These populations of white spruce are relatively small, slow growing, and generally not commercially valuable.

The response of treeline white spruce populations to climate change is of particular interest because this species delimits much of the North American treeline (Sirois, 1999) and the performance under warmer conditions of present-day populations is an indication of the possible future effects of climate change. In a large (>1500 trees) sample of treeline white spruce across the mountains of the Brooks and Alaska Ranges, over 40% displayed a statistically significant negative growth response to summer warmth while slightly fewer than 40% had a positive response to late spring warmth (Wilmking et al., 2004). In the negatively responding (warmer = less growth) white spruce population, July temperature explained most of the variability in growth. Growth was strongly reduced at temperatures above a July threshold of about 16 ºC at the Fairbanks International Airport climate station, which served as a representative common reference (temperatures were estimated to be 3 to 4 ºC cooler at the various treeline sites). Growth of positive responders is correlated to March or April temperature, and the relationship is generally not significant until the second half of the 20th century (Wilmking et al., 2004). D'Arrigo and Jacoby (Lamont-Doherty Earth Observatory, Columbia University, pers. comm., 2003) found a similar dual response in white spruce in the Wrangell St. Elias Mountains of Alaska. A study of eight sites at and near alpine and arctic treeline in three regions of Alaska found mixed populations of temperature response types as well, and growth decreased in response to increasing temperatures at all but the wettest sites after 1950 (Lloyd and Fastie, 2002). The negative growth response to temperature is more common in contiguous stands and tree islands (clusters of trees) than in isolated individual trees (Lloyd and Fastie, 2002; Wilmking et al., 2004). The intensity of the negative effect of July warmth increased after 1950, directly reflecting July temperatures above the threshold in a greater number of years in the second half of the 20th century compared to the first half (Wilmking et al., 2004).

The explanation for reduced growth in treeline white spruce with warming is that negative responders are experiencing temperature-induced drought stress, while the positively responding trees are not (Jacoby and D'Arrigo, 1995; Juday et al., 2003; Wilmking et al., 2004). At some treeline sites in northern Alaska, individual trees have shifted their response to climate during their lifetimes, following the regime shift to warmer conditions that took place in the last decades of the 20th century (Jacoby and D'Arrigo, 1995). Whereas previously the growth of the tree responded positively

to summer temperature, it either became insensitive or began responding negatively to summer temperature after the shift to the warmer regime.

These results establish that from an ecological perspective, recent climate warming has been a major event that has strongly affected the growth performance of the majority of white spruce at and near treeline in Alaska and almost certainly in similar climate zones in Canada. The five ACIA-designated models project July temperatures by the mid- to late 21st century that the empirical relationship associates with very low or no growth in negatively responding white spruce. This suggests that under the ACIA-designated model projections, it is possible that the northern white spruce tree limit in Alaska and adjacent Canada would not readily advance. At the least, treeline is likely to become much more complex, with negative responders disappearing and positive responders expanding. It is possible that novel conditions would emerge, such as a portion of the southern tundra boundary in North America that is separated from the boreal forest by aspen parkland (see Fig. 14.1; Hogg and Hurdle, 1995). The actual response of treeline white spruce in this part of the world also adds support to the suggestion that aridification could be a major issue under climate scenarios projected by the ACIA-designated models.

14.7.3.2. Black spruce in Alaska and Canada

Stands dominated by black spruce represent about 55% of the boreal forest cover of Alaska and a large fraction of the northern boreal region of Canada. The response of black spruce to climate has not been studied as extensively or for as long as white spruce, so the literature on climate/growth relationships is more limited. This section draws on some recent dendrochronology work in Interior Alaska.

Different temperature factors are associated with black spruce growth on different permafrost-dominated sites (Fig. 14.20), a more variable response than the consistent temperature/growth response in upland white spruce (section 14.7.3.1). Of four sites examined, three show a negative growth response to increasing temperature, while one shows a positive response (Fig. 14.20). Both the Toghotthele site (Fig. 14.20a) and the Zasada Road 10 site in the Bonanza Creek Long Term Ecological Research site (Fig. 14.20c) show a negative growth response to summer temperatures (year of growth and 2 years prior). Radial growth of black spruce at both the northern and southern BOREAS sites in western Canada was also negatively related to summer temperature, or conversely, favored by cooler and wetter conditions (Brooks et al., 1998).

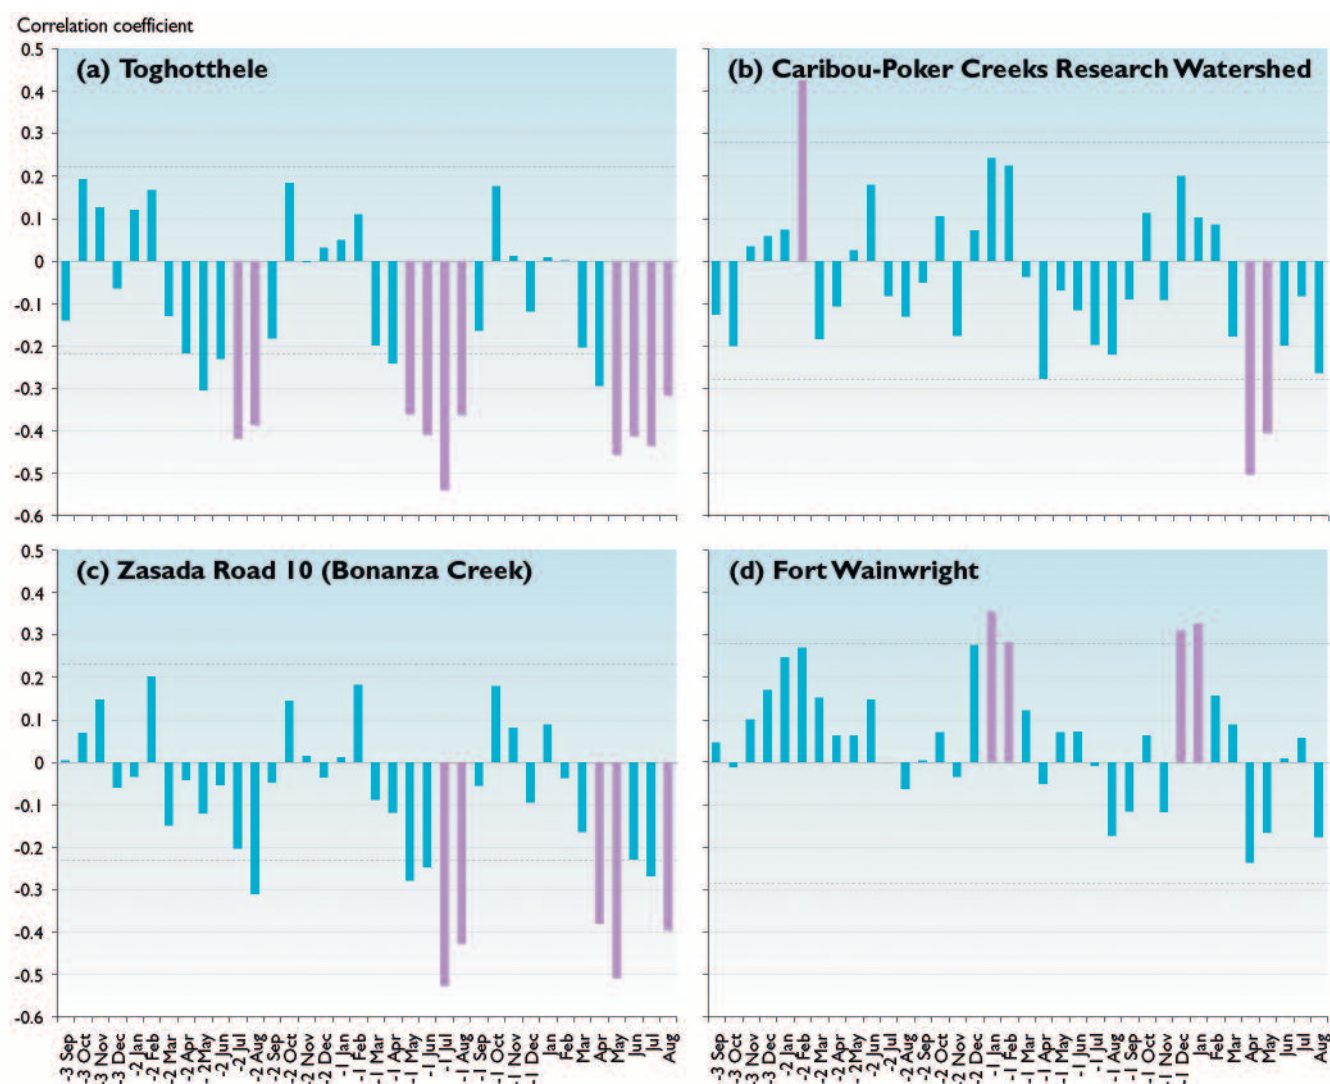
Black spruce at the Caribou-Poker Creeks Research Watershed (CPCRW) show both a negative correlation to April and May temperatures during the growth year and a positive correlation to February temperature two years prior to growth (Fig. 14.20b). A simple two-


Fig. 14.20. Correlation of black spruce radial growth and Fairbanks mean monthly temperatures from four permafrost-dominated sites in central Interior Alaska. Lavender bars indicate a statistically significant correlation between the mean monthly temperature and tree growth, while blue bars indicate that the correlation is not statistically significant. Negative numbers preceding months on horizontal axis represent years before the year in which growth occurred (data from Juday and Barber, 2005).

month index of the mean of April and February temperature is highly correlated to the growth of the CPCRW trees (Fig. 14.21). The negative effect of warm early-spring temperatures on growth at CPCRW can be attributed to the onset of photosynthesis in spring when the ground is still frozen, causing desiccation and damage to the needles (Berg E. and Chapin, 1994) early in the growing season. The smoothed (5-year running mean) values are highly correlated during the 20th century (r=0.86), suggesting that tree growth of this species at sites similar to these could be projected using the ACIA-designated scenarios. While warm February temperatures favor growth, warmth in April depresses growth. With substantial temperature increases in the late 20th century, growth of this species has declined because the negative influence of April is stronger.

Growth of black spruce trees at Fort Wainwright is positively correlated with winter temperatures (Fig. 14.20d). When January in the year of growth and December, February, and January in the year prior to growth were all

Fig. 14.21. Relationship of radial growth of black spruce at Caribou-Poker Creeks Research Watershed to the mean of April (growth year) and February (two years prior) temperature, smoothed with a 5-year running mean. Temperature axis is inverted as in Fig. 4.18 (data from Juday and Barber, 2005).

Fig. 14.22. Relationship of radial growth of black spruce at Fort Wainwright, Alaska (n=20 trees), to a 4-month climate index (mean of monthly temperature at Fairbanks, Alaska, in January of growth year and January, February, and December of previous year). Scenario lines show projections of the 4-month climate index (data from Juday and Barber, 2005).

warm, the trees grew better (Fig. 14.22). The smoothed (5-year running mean) values are highly correlated during the 20th century. This is one of the few species and site types in central Alaska for which the empirically calibrated growth rate can be inferred to improve under projected higher temperatures.

The positive relationship between monthly temperatures and black spruce growth at the Fort Wainwright site suggests that growth of tree on sites similar to it is very likely to increase (Fig. 14.22). The ECHAM4/OPYC3 model projects especially strong warming for the Fairbanks grid cell in the winter months that best predict black spruce growth at the site, so the empirical relationship, if it were maintained, suggests a major
Fig. 14.23. Relationship between summer temperatures (mean of May and June in growth year, and June and July of the previous year) at Fairbanks and relative growth of black spruce at the Toghotthele site in central Alaska, and projections based on climate scenarios. Temperature axis is inverted as in Fig. 14.18 (data from Juday and Barber, 2005).

increase in growth rate (Fig. 14.22). Black spruce at the Fort Wainwright site occupy a low productivity system, so the overall significance of the projected growth increase is not clear. The CSM_1.4 model projects winter temperatures that do not increase as rapidly or to as great a degree, so the modeled relationship of these positively responding spruce suggests only a modest increase in growth under that scenario. Presumably, the positive effect of warm winter temperatures on growth is experienced though control of active-layer rooting depth and soil temperature in this permafrost-dominated ecosystem. However, well before the end of the scenario period, the CGCM2 (Fig. 14.9) and all the other models project mean annual temperatures above freezing in this grid cell. If temperatures increase to that extent, the temperature/growth relationship depicted in Fig. 14.22 is not likely to persist. However, this permafrost site is very near thawing, and warming of the magnitude projected by the ACIA-designated models would probably initiate thawing during the 21st century, leading to widespread ground subsidence and tree toppling, representing a new challenge for the survival of this species on such sites. Once the soil thawing process is complete, species with higher growth rates than black spruce, such as white spruce or paper birch, are likely to have a competitive advantage on the transformed site.

For the Toghotthele site (Alaska Native-owned land; Toghotthele Corporation), model projections of future temperature were compared to the empirical record of black spruce growth (Fig. 14.23) similar to the approach used for white spruce (section 14.7.3.1). The mean of four summer months is an excellent predictor of tree growth, with warm years resulting in strongly reduced growth. As for white spruce, the results suggest that if climates similar to those projected by the ACIA-designated models actually occur, by the end of the 21st century black spruce would experience climates that are very unlikely to permit the species to survive on similar types of sites. In this case, the CSM_1.4 model projects the highest levels of the particular set of monthly temperatures that drives the relationship while the CGCM2 model projects slightly lower levels. However, in both scenarios, warmth in individual years produces an empirical relationship very near zero growth before the end of the scenario period. Allowing for some differences in calibration and degree of climate control, the generally similar growth of black spruce in the BOREAS study areas suggests that elimination of black spruce is very likely to be widespread across the western North American boreal forest.

14.7.3.3. Scots pine in Scandinavia

Growth responses of Scots pine at the tree limit in the central Scandinavian Mountains varied throughout the 20th century (Linderholm, 2002). Long, hot, and dry summers have traditionally been thought to be optimal for pine growth in that environment. The greatest pine growth of the past three centuries occurred during the

decade from 1945 to 1954. Although summer temperature was not particularly high during the mid-20th century, higher than average spring and autumn temperatures that extended the growing season were inferred to be the cause of this decade of high Scots pine growth (Linderholm, 2002). Despite similar apparently favorable temperature conditions in the latter part of the 20th century, growth of this species on similar sites declined during the most recent warmth. This suggests the occurrence of some additional unique component of the recent warming that negated the previously positive influence of extended growing seasons.

In addition to north–south transects of tree-ring chronologies, an east–west transect has been developed in Fennoscandia (Linderholm et al., 2003). Nine tree-ring width chronologies for Scots pine were compared for growth variability and response to climate along a gradient of maritime to continental conditions in central Fennoscandia. The study revealed higher growth variance and stronger response to climate in the oceanic area west of the Scandinavian Mountains, compared to the more continental areas further east. Pine growth responded positively to elevated summer temperatures in the western areas, and positively to high summer precipitation in the east. Generally, pine growth showed a weaker relationship with the North Atlantic Oscillation (section 2.2.2.1) than with temperature and precipitation. During the last half of the 20th century, pine growth in western Fennoscandia displayed reduced sensitivity to climate, while in the east, growth sensitivity increased. Indications of growth stress were found in one site east of the Scandinavian Mountains. Increasing temperatures have been accompanied by increasing precipitation in Fennoscandia throughout the 20th century, and it was suggested that a change in climate regime from subcontinental to sub-maritime caused those trees to experience climatic stress (Linderholm et al., 2003).

A selection of Scots pine tree-ring width chronologies was collected from across Sweden (Fig. 14.24). The standardized chronologies include wet (peatland) and dry (mineral soil) growth environments (Table 14.7). Despite large differences in climate responses among the sites, the collective growth trend for all the sampled Scots pine in the last few decades of the 20th century is negative (Fig. 14.25). Furthermore, a common feature is distinct changes in growth sensitivity to climate at all sites during that period, a feature that has also been observed at several other Fennoscandian sites. The pattern is one of widespread and simultaneous decreases in growth, and a decreased ability of previously established climate factors to project growth as accurately.

Because precipitation, in addition to temperature, has increased over the past decades in Scandinavia, it is unlikely that drought stress is the main reason for decreasing Scots pine growth throughout Sweden. The one exception is northernmost Sweden, where growth responses to summer temperatures are decreasing and responses to autumn precipitation increasing. However, in central Sweden, the evidence suggests a different cause of reduced growth and changing climate responses. On the eastern slopes of the Scandinavian Mountains, the climate could be regarded as subcontinental, with low annual precipitation and high temperature amplitude over the year. Tree-ring data from sites east of the mountains implies that over the past decades, the climate of this area has become more maritime, and consequently the trees may have suffered stress from surplus moisture rather than drought

Fig. 14.24. Location of 14 Scots pine ring-width chronologies (see Table 14.7 for key to locations).

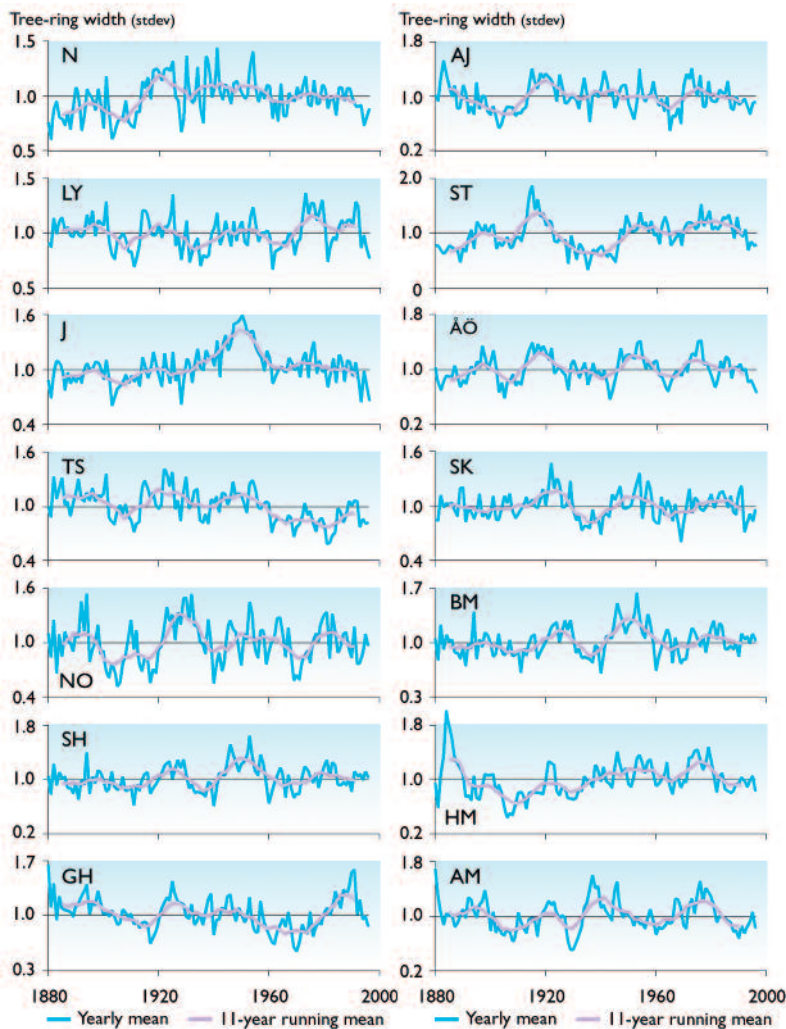

Fig. 14.25. Standard chronologies of Scots pine ring width (age de-trended and normalized with long-term mean set to 1.0 and standard deviation on 1.0) in Sweden. Curves express the degree of growth at any time relative to the long-term mean of the sample (see Table 14.7 for key to locations; data from Linderholm, 2002; Linderholm et al., 2002, 2003).

(Linderholm et al., 2003). In conclusion, the observed change in tree growth patterns and growth/climate relationships is most likely an effect of contemporary climate change. How trees respond to increased temperatures and/or precipitation is dependent on the local climate, and it seems that trees in oceanic areas are less affected than are those where the local climate regime has shifted from subcontinental to sub-maritime.

14.8. Climate change and insects as a forest disturbance

14.8.1. Role of insects in the boreal forest

The boreal forest is naturally subject to periodic large-scale tree mortality from insect outbreaks. The death of attacked trees has a considerable influence on the balance of carbon sequestered by forests. In boreal forests of Canada, insect-caused timber losses (tree death) may be up to 1.3 to 2.0 times greater than the mean annual losses due to fires (Volney and Fleming, 2000). The particular insects involved in large-scale boreal outbreaks

include bark and wood-boring beetles, defoliating insects (often Lepidoptera – moths and butterflies), and insects that attack roots and cones. Major population increases of these insects (irruptions), along with wildland fires, are the major short-term agents of change in the boreal forest. Insect-caused tree mortality can appear suddenly and within 1 to 10 years affect hundreds of thousands to millions of hectares of boreal forest in an outbreak or related series of outbreaks. Moderate to severe defoliation of trees by insects has affected nearly 16 million ha/yr in the province of Ontario since 1975 (Parker et al., 2000). Nearly all boreal forest regions are subject to this phenomenon, and it may represent an adaptive response in which simultaneous mass tree death helps create conditions for the renewal of site productivity through processes that warm soils, mobilize nutrient elements, and promote simultaneous tree regeneration.

The peculiar vulnerability of boreal forests to large-scale insect disturbance may also be related to the low biodiversity of both the host tree populations (limited number of species) and the limited diversity within the complex of tree-attacking insects and the populations of predators and parasites that work to stabilize their numbers. Ecological theory predicts that systems with few species should be less stable or buffered against major population swings, and of the major forest regions of the world, the boreal forest is the least species-rich in most taxonomic groups. Finally, the occurrence of tree hybrids may be a non-climatic risk factor for large-scale insect outbreaks. Where the distributions of two wind-pollinated tree species of the same genus (e.g., spruce, pine, larches) approach each other or overlap, the trees can interbreed and form hybrid offspring. Because the hybrid trees contain a random assortment of the genes of both parents, they seldom inherit highly integrated and complete defense traits against insect attacks, such as specific chemical defenses or timing of events to avoid vulnerability. As a result, tree defenses against insect attack may be lowest in hybrid zones (Whitham, 1989; Whitham et al., 1994).

The level of tree mortality caused by insect outbreaks can vary from selective removal of a few percent of dominant trees to the death of nearly the entire forest canopy. Although vulnerable tree species and age classes must be present for insect outbreaks to occur, climatic events are often the trigger or proximate cause of the insect population increases and associated widespread tree mortality. In general, many organisms in the boreal region, and especially the northern boreal forest region, are heat-limited, that is, they could perform (survive, grow, and reproduce) better with more

warmth if other factors did not become limiting. Many insect agents of tree mortality in the northern boreal region are heat-limited, so that sustained periods of abnormally warm weather are often associated with irruptions of insects that attack boreal tree species. Given that this is a natural climate-driven system, it is important to distinguish climate change effects from natural operation of this system.

Generally, a climate change effect imposed on the natural insect/tree-death system is very likely to result in a greater frequency of insect outbreaks; more extensive areas of tree mortality during outbreaks; and greater intensity of insect attack resulting in higher average levels of tree death within outbreak areas. The sustained operation of these factors as a result of temperature increases, if they occur, is very likely to begin to change regional tree species composition within decades. A necessary confirmation of the occurrence of a specific climate change effect on the insect/tree-death process would include the detection of differences between the composition of the new, altered forest and historical and recent paleo-ecological records of previous generations of forest. An alternative possibility that needs to be considered is that temperature increases (along with increased precipitation) will possibly produce a more favorable growth environment for certain tree species on certain site types. The increased vigor of the trees is very likely to increase their ability to produce defensive compounds and successfully resist the similarly likely increased levels of insect attacks.

It is possible that the influences of climate warming on forests and on tree-hosted insects (positive and negative for forest health) could occur simultaneously in different locations of the boreal forest, or could occur sequentially in one place at different magnitudes and rates of temperature increase. As a result, temperature increases could be associated with improved forest health in some locations and forest health problems elsewhere, and the climate change effect at any given time would be the sum of these two outcomes. In addition, the initial stage of temperature increases would produce one profile of the balance of forest health outcomes across the area of analysis, but later stages representing greater temperature increases would shift the previous balance of forest health outcomes. The empirical record strongly suggests overall negative effects on boreal forest health from sustained temperature increases.

14.8.2. Spruce bark beetle in Alaska

During the 1990s, the Kenai Peninsula in south-central Alaska experienced the largest outbreak of spruce bark beetles (*Dendroctonus rufipennis*) in the world (Werner, 1996). The forests of the Kenai lowlands are transitional between coastal Sitka spruce (*Picea sitchensis*) rainforests and the white spruce–paper birch boreal forests of semi-arid central Alaska. From 1989 to 1999, more than 1.6 million ha of mature forest made up of white spruce and hybrids of Sitka and white spruce (called Lutz

spruce) in south-central Alaska experienced at least 10 to 20% tree mortality, the threshold level for aerial mapping detection. In much of the insect outbreak area, virtually all mature canopy trees were killed. Extensive logging was initiated to salvage beetle-killed timber on private lands, and the US federal government has found it necessary to appropriate funds to reduce fuel hazards in stands with numerous dead trees after infestation.

The first documented spruce bark beetle infestation on the Kenai Peninsula occurred in 1950. Local infestations occurred throughout the 1950s and 1960s on the northern Peninsula (Holsten, 1990). A major outbreak in the northern Peninsula that started in 1970 prompted the US Forest Service to initiate annual surveys in 1971, which have continued with few interruptions. Annual survey maps show that spruce bark beetles are endemic to Kenai Peninsula forests, at least under the present climatic regime. In any given year, there is always a background level of infestation somewhere in south-central Alaska, with periodic major outbreaks in some years.
The relationship of spruce bark beetle to climate involves two direct temperature controls over populations of the insect, and an indirect control through host tree resistance. Two successive cold winters depress the survival rate of spruce bark beetle to such a low level that there is little outbreak potential for the following season (Holsten, 1990). The spruce bark beetle is a heat-limited organism on the Kenai Peninsula and normally requires two summers to complete its life cycle. During abnormally warm summers on the Kenai Peninsula, the spruce bark beetle can complete its life cycle in one year, dramatically increasing the potential for population buildup (Werner and Holsten, 1985). Tree health increases host resistance to beetle attack: healthy spruce trees can successfully resist moderate numbers of beetle attacks by opposing the wood-boring activity of females entering the tree to lay eggs with pitch under high turgor pressure (Holsten, 1990). The beetles are unable to overcome the flow of pitch and either are expelled or succumb in their pitch tubes. Host trees that are under stress, including either climate stress or stress from mechanical breakage, have reduced growth reserves, less pitch, and lower turgor pressure, and so are less able to resist spruce bark beetle attacks. When regional events stress entire populations of trees, spruce bark beetle reproductive success is greatly increased.

The US Forest Service conducts annual aerial surveys for "red needles" (i.e., conifer needles dead for a year or less) that allow areas of spruce killed by spruce bark beetle within the previous year to be mapped. These annual surveys describe the areal extent of active infestation; densities of recently killed trees can range from a few stems to hundreds of stems per hectare (USDA Forest Service, 1950-1999). There is a one- to three-year lag between beetles entering a stand and a stand-wide flush of red needles (tree death). Typically, a sequence of red-needle acreage maps on the Kenai Peninsula will show a rise and fall of active infestation

over a 5 to 10 year period on a scale of 100 to 1000 ha. After that time, nearly all white/Sitka/Lutz spruce greater than 12 cm in diameter will generally be dead in the affected stand, and subsequent surveys will record no more red-needle acreage for that stand.

Following the 1976–1977 increase in North Pacific sea surface temperatures (Mantua et al., 1997), mean annual and summer temperatures in the Kenai Peninsula lowlands rose 0.5 to 1.5 °C. This temperature increase is the latest acceleration of post-LIA climate warming in south-central Alaska (Jacoby and D'Arrigo, 1995; Wiles et al., 1996). Until recently, the most visible manifestation of the late 20th-century warming was a drying landscape, with dried-up ponds, falling water levels (as much as 1 m) in closed-basin lakes, and black spruce invasion of peat wetlands across the landscape.

Annual red-needle acreages for the southern Kenai Peninsula can be compared with standardized climate

parameters recorded at the Homer Airport climate station (Fig. 14.26). In Fig. 14.26c, the drought index is calculated by subtracting the normalized past October to present September total precipitation from the normalized May through August mean temperature of the named year. The drought index is designed to combine the moisture contribution of the previous winter with the growing season moisture and temperature of the identified year. The first major spruce bark beetle outbreak of the post-1950 period occurred in the early 1970s, following the extremely warm and dry period of 1968 to 1969 on the northern Peninsula (Fig. 14.26). Red-needle mortality dropped to nearly zero by 1975, following three cool summers (1973–1975). On both the northern and southern Peninsula, the sustained onset of warm summers beginning in 1987 was followed by substantial increase in red-needle mortality beginning in 1990 and reaching a maximum in 1996. Annually mapped red-needle area declined after 1996 on the southern Peninsula because beetles had killed most of the available mature spruce forest, not because climatic factors became less favorable for insect population increases.

The association of red-needle mortality with drought is particularly striking in the southern Peninsula forests between 1989 and 1997 (Fig. 14.26c,d). Spruce bark beetles first attack the large, slowly growing trees in a stand (Hard, 1985, 1987). The survival of smaller trees (both young saplings and released understory pole-size trees) is attributed to their ability to produce enough pitch to swamp the beetle galleries and kill the larvae. An additional factor may be that large trees are more prone to drought stress. Due to cold soils, spruce trees in Alaska usually root within the upper 30 to 40 cm of the soil and extend their roots laterally for 1 to 2 m. This shallow, extended rooting can bring trees into competition with neighboring trees and surface vegetation, especially in times of drought. Ring widths in many large trees generally decline for 5 to 10 years prior to the tree succumbing to bark beetles, clearly signifying a stressed condition. Drought is the most likely source of this stress (Fig. 14.26, Hard, 1987).

While warm summers are the proximate cause of outbreaks, spruce stands must reach a certain level of maturity before serious spruce bark beetle infestation can develop, regardless of summer temperatures. For example, relatively light levels of tree mortality from bark beetles occurred in an area near the headquarters of the Kenai National Wildlife Refuge that burned in 1926, while a nearby stand of spruce 125 years old or older experienced heavy mortality. Many stands on the southern Kenai Peninsula were composed of trees that regenerated following a moderate spruce bark beetle outbreak in the 1870s and 1880s, and those trees only matured to a condition that would support substantial spruce bark beetle infestations in the mid-20th century. By the time that warm summers began in 1987, these trees had once again become prime bark beetle habitat.

Fig. 14.26. Timing of climate events that release spruce bark beetles from population limits showing (a) mean summer (May–Aug) temperature; (b) mean annual temperature; and (c) drought index, compared to (d) actual outbreaks of bark beetles (represented by "red-needle" area) during the 20th-century period of record (data from E. Berg, Kenai National Wildlife Refuge, Soldotna, Alaska, pers. comm., 2002; NOAA, 2002 (Homer Airport station); Wittwer, 2004).

Moisture appears to be another important factor in spruce bark beetle outbreaks on the Kenai Peninsula. Precipitation at the Kenai Airport station reached a record low from 1967 to 1969, and was at a near-record low (to that date) at the Homer Airport station during that period. This dry period was followed by an intense but short-lived spruce bark beetle outbreak from 1970 to 1974 (Fig. 14.26c,d). It appears that at least two warm summers are required to initiate a spruce bark beetle outbreak. This is consistent with the life cycle of the beetles, which normally takes two years to complete, except in the warmest summers when it can be completed in one year (Werner and Holsten, 1985). In 1987, summer temperatures shifted above the mean (Fig. 14.26a), beginning a sustained series of warm summers that is unique in both the instrumental and local reconstructed temperature records. After 1987, the spruce bark beetle outbreak accelerated, and no period of several cool summers, which could thermally arrest the outbreak, has occurred to the present. Red-needle acreage, however, has dropped steadily since 1996 because most of the mature spruce forest has been killed. Food supply, rather than climate, appears to have been the ultimate limiting factor in this outbreak, unlike outbreaks during the past 200 to 250 years studied by staff of the Kenai National Wildlife Refuge.

These results suggest that there is a continuing high risk from climate change to the management of forest land in south-central Alaska for spruce forest crops. Under recent climate conditions, and especially under scenarios of further temperature increases, spruce bark beetle irruption potential is very likely to remain high. As the small surviving (understory) spruce trees in the region mature to commercial forest dimensions, they will move into the prime size and age classes to serve as hosts for spruce bark beetle. Under these circumstances, the regional environment is very likely to remain effectively saturated with spruce bark beetles because climate limitations on beetles have been removed. Investments in regeneration and early tending of new commercial stands of spruce, should that be desired, would carry considerable risk because bark beetles would become effective agents of tree mortality at about the time that stands of spruce became large enough to generate commercial value.

14.8.3. Spruce budworm in North America

The eastern spruce budworm (*Choristoneura fumiferana*), is a defoliating insect affecting conifer trees, generally in the southern and central boreal region of the United States and Canada. The absolute distribution limits of spruce budworm generally follow that of white spruce throughout the boreal forest, and there are records of severe defoliation within 150 km of the Arctic Circle (Harvey, 1985). Outbreaks have at times extended over 72 million ha and lasted for up to 15 years (Fleming and Volney, 1995). The budworm is generally present in the forest at low background numbers. During irruptions, there can be more than 22 million budworm lar-

vae per hectare in suitable forest stands (Crawford H. and Jennings, 1989).

Weather appears to be a critical factor in determining budworm distribution. Irruptions of budworm generally follow drought, and outbreaks also start after hot, dry summers (Fleming and Volney, 1995). Drought stresses the host tree population, reducing host resistance (Mattson and Haack, 1987). Elevated summer temperatures increase budworm reproductive output. Female budworms lay 50% more eggs at 25 °C than at 15 °C (Jardine, 1994). Finally, higher temperatures and drought can shift the timing of budworm reproduction so that natural parasitoid predators are no longer effective in limiting budworm numbers (Mattson and Haack, 1987). Conversely, cold weather can stop a budworm outbreak. Budworms starve if a late spring frost kills the new shoot growth of the host trees on which the larvae feed.

Given this weather/climate sensitivity of budworm, it was inferred that a warming climate would be associated with northward movement of spruce budworm outbreaks (Gitay et al., 2001). Such a northward movement appears to have happened. Before about 1990, spruce budworm had not appeared able to reproduce in the northern boreal forest of central Alaska. In that year, after a series of warm summers, a spruce budworm irruption occurred in the Bonanza Creek Long-Term Ecological Research site and visible canopy damage spread over tens of thousands of hectares of nearby white spruce forest. Populations of budworm have persisted in this area near the Arctic Circle, including a minor outbreak in 2002–2003.

14.8.4. Other forest-damaging insects in North America

Aspen is the most important deciduous tree species in the Canadian boreal forest, with more than 1000 Tg of carbon stored in the aboveground biomass. Aspen dieback has become conspicuous over parts of the southern boreal forest and aspen parkland in western Canada. In 18 aspen stands near Grande Prairie, Alberta, defoliation histories were reconstructed based on tree rings and records of past insect outbreaks. Several factors contributed to the observed dieback. Defoliation by the forest tent caterpillar (*Malacosoma disstria*) and drought in the 1960s and 1980s led to reduced growth and predisposed some stands to secondary damage by wood-boring insects and fungal pathogens. Thaw–freeze events during a period of unusually light late winter snow cover (1984–1993) also contributed to the observed dieback. Under climate warming, the severity of these stressors is very likely to increase, which would pose a serious concern for the future health, productivity, and carbon sequestration of aspen forests in the region (Hogg et al., 2002).

During the last two decades of the 20th century, warmer summers and winters in central Alaska were associated

with a noticeable increase in the area of trees killed or damaged by insects. The mapped area of forest affected by spruce budworm, spruce coneworm (*Dioryctria reniculelloides*), and larch sawfly (*Pristiphora erichsonii*) defoliation mapped throughout Interior Alaska increased, totaling over 300 000 ha of combined infestations during the period 1991 to 1996 (Holsten and Burnside, 1997).

Various insects are known have the potential to become serious agents of tree mortality in a much warmer boreal and arctic region. Insect species not currently present are almost certain to be able to disperse readily into the region if higher temperatures allow, and some are likely to develop outbreak potential. In Ontario, Canada, forest land managers estimate that a range of forest-damaging insects that are currently prominent in the central and southern boreal area would move northward or, if already present, develop greater outbreak potential (Parker et al., 2000). These include spruce budworm, forest tent caterpillar, jack pine budworm (*Choristoneura pinus pinus*), and gypsy moth (*Lymantria dispar*). The bronze birch borer (*Agrilus anxius*) is a North American species that can cause severe damage to paper birch and may be effective in limiting the survival of birch along the southern (warm) margin of its distribution (Haak, 1996). The bronze birch borer is present today in small numbers as far north as Alaska. The ACIA-designated models project temperatures in northern boreal North America near the temperatures of areas where the bronze birch borer effectively limits birch today. In boreal Alaska, a larch sawfly outbreak killed most of the larger and older tamarack (*Larix laricina*) trees during a warm period in the decade of the 1990s, and aspen leaf miner (*Phyllocnistis populiella*) appeared at outbreak levels (142 000 ha) by 2003 (Wittwer, 2004).

14.8.5. Tree-damaging insects in northern Europe

Several insect species with tree hosts in northern European boreal forests regularly undergo population outbreaks, and most have some connection to direct or indirect effects of warm weather anomalies and temperature limitation. In Europe, temperature increases, especially in the form of warmer winters, are associated with increased outbreaks of various species of bark beetles and aphids (Beniston et al., 1998). Bark beetles (Coleoptera, Scolytidae) are present in the boreal region of northern Europe. A key feature of temperature sensitivity is the timing of the first flight of mature adults in the spring as they seek new host trees to attack. Many beetles do not begin spring flight until air temperature reaches a threshold level. The bark beetle *Ips typographus* (spruce engraver beetle) built up in numbers in trees damaged by heavy storm and snow damage in the late 1960s, and then broke out in large numbers during a series of warm years in the early 1970s (Heliövaara and Peltonen, 1999). A similar combination of widespread tree host susceptibility and warm summers in the future is very likely to result in similar out-

breaks and tree death. There are no examples in Europe of bark beetles simultaneously expanding their distribution in one direction and retracting in another (Heliövaara and Peltonen, 1999).

Tree-defoliating insects that are responsive to temperature increases are capable of causing large-scale tree death and injury in the northernmost forests of Europe (Bylund, 1999; Danell et al., 1999). Geometrid moths of two species occur in the mountain birch (*Betula pubescens* ssp. *czerepanovii*) forest that makes up the ecotone between boreal forest and the tundra of Fennoscandia. The autumnal moth (*Epirrita autumnata*) and the winter moth (*Operophtera brumata*) regularly reach outbreak levels. Although both species lay eggs on a variety of trees and shrubs, the main host is mountain birch. Outbreaks of the autumnal moth mainly occur in mature forests in inland locations, whereas winter moth outbreaks are restricted to warm south-facing slopes or warmer locations along the Norwegian coast (Neuvonen et al., 1999).

Populations of both the winter and autumnal moth fluctuate from low to high levels with 7 to 12 years between peak densities (Altenkirch, 1990). Severe defoliation causes death of older stems, which usually triggers vigorous sprouting of new stems from the base of the tree. However, the recovery process in these forests is slow, and may take about a century (Bylund, 1999). Particularly severe defoliation may kill the underground portions of the tree as well. The natural cyclic fluctuation of geometrid moth numbers is driven by density-dependent factors that lag outbreaks in time, including buildup of natural enemies, disease, and reduced food quality, and by weather conditions at all life stages. As do many of the macrolepidoptera, autumnal moths overwinter as eggs, making them vulnerable to extreme cold temperatures that reduce survival, particularly egg masses placed in the tree canopy above the snow limit. From 1960 to 1990, minimum winter temperatures below -36 °C, along with fine-scale patches of trees on dry and nutrient poor soils, efficiently predicted the distribution of autumnal moth outbreaks in birch forests of Finland (Neuvonen et al., 1999). Climate change involving an increase in minimum winter temperatures is likely to increase the frequency, and possibly the severity, of outbreaks of this species and others that overwinter as eggs (Neuvonen et al., 1999). Warmer summer temperatures with no change in winter temperatures are likely to reduce the geometrid moth outbreak potential, because higher densities of moth predators associated with warm summers would partially protect birch, while the winter limitation on the moths would still operate. Finally, if climate change consists of warmer summers and winters, as projected by the ACIA-designated models, current insect population/ ecological models are not adequate to project overall effects on outbreaks (Neuvonen et al., 1999), although new insect distributions and novel climate limitations and outbreak patterns are very likely under such circumstances (see also section 7.4.1.4).

A diprionid sawfly (*Neodiprion sertifer*) is the most serious defoliator of pine forests in northern Europe. Outbreaks mostly occur on dry and infertile sites. Minimum winter temperatures below -36 ºC also limit this species. Outbreaks in Finland have been most frequent in southern and central inland areas, and temperature increases are likely to make outbreaks more common in eastern and northern areas (Neuvonen et al., 1999).

14.9. Climate change and fire

Fire is a major climate-related disturbance in the boreal forest, with pervasive ecological effects (Payette, 1992; Van Cleve et al., 1991; Zackrisson, 1977). Climate, disturbance, and vegetation interact and affect each other, and together they influence the rate and pattern of changes in vegetation (Neilson, 1993; Noble, 1993), the rate of future disturbance (Gardner et al., 1996; Rupp et al., 2002; Turner M. et al., 2003), and the pattern of new forest development (Turner D. et al., 1995; Rupp et al., 2000a,b). Understanding these interactions and feedbacks is critical in order to understand how scenarios of climate change will affect future fire regimes and the consequences these ecological changes will have for both boreal forests and forest management.

The total area burned in North America has been increasing concurrently with recent temperature increases and other climatic changes (Stocks et al., 2000). The annual area burned in western North America doubled in the last 20 years of the 20th century (Murphy et al., 2000). Based upon less precise statistics there appears to be a similar trend in the Russian Federation (Kasischke et al., in press).

Three factors are important when examining the impacts of climate change on the fire regime. First, boreal forests become increasingly flammable during succession as the forest floor and understory builds up. Conifer-dominated stands are usually more flammable than broad-leaved and other vegetation types. Early post-fire vegetation is generally less flammable than vegetation that is older and more structurally complex. Vegetation also influences fire probability indirectly through its effects on regional climate (Chapin et al., 2003), with early successional stands absorbing and transferring only half the incoming solar radiation compared to late successional spruce stands (Baldocchi and Vogel, 1995). A second factor is the need to understand the direct effects of climate on the fire regime. Finally, humans and their land-use changes affect the fire regime, and these changes must be considered to understand future fire effects in a warmer climate.

14.9.1. The role of fire in subarctic and boreal forest

Disturbance is the driving force behind vegetation dynamics in the boreal biome. Wildfires, alluvial processes (i.e., erosion and flood deposition), tree-fall events caused by wind, and tree-killing insect outbreaks all play major roles that can affect large portions of the landscape. However, fire is particularly significant because of its pervasive presence, its strong link to climate, and the direct feedbacks it has to permafrost dynamics, regional climate, and the storage and release of carbon. Fire often follows large-scale tree death caused by other factors.

In the mosaic of old burns that covers the boreal forest landscape, there are four tendencies related to ecosystem development, expressed over timescales of decades to millennia and over differing landscape areas. There is a tendency towards paludification, which is the waterlogging and cooling of soil caused by the buildup of organic soil layers (Viereck, 1970). Paludification can be a significant factor in treeline retreat in maritime climates (Crawford R. et al., 2003). A second tendency is for the longer-lived conifer species to usurp the canopy from shorter-lived hardwood species (Pastor et al., 1999; Van Cleve et al., 1991) with an accompanying decline in living biomass (Paré and Bergeron, 1995). The third tendency is towards the formation of a shifting-mosaic steady state in which burned areas at different stages of secondary succession form the pieces of the mosaic (Wright, 1974). Finally, there is a tendency toward increased risk of burning with age. Fire opposes paludification by oxidizing the organic matter buildup on the ground surface (Mann D. and Plug, 1999). Fire also interrupts conifer take-over by restarting successional development with the earliest broadleaf-dominated stages. In addition, because the time since the last fire is an important determinant of vegetation composition and soil conditions, fire frequency has a large influence on carbon storage and release within the boreal forest (Kasischke et al., 1995; Kurz and Apps, 1999).

Fire is strongly controlled by both temporal and spatial patterns of weather and climate (Flannigan and Harrington, 1988; Flannigan et al., 2001; Johnson, 1992). Specific fire behavior responds to hourly, daily, and weekly weather conditions. Solar radiation, continentality, topography, and specific terrain features influence these fire-generating conditions. The general fire regime of an area responds to long-term, landscape-level climatic patterns. As climate varies, the controlling weather variables can vary in magnitude and direction (Flannigan et al., 2001).

Case studies from northern coniferous forests have documented weather variables prior to and during specific fire events (Flannigan and Harrington, 1988) and have identified good predictors of conditions that promote the rapid spread of fire. These conditions include warm temperatures, little or no precipitation, low relative humidity, and high winds. Synoptic weather conditions that produce cold frontal systems, drought, and low relative humidity have been found to be good predictors of area-burned activity (Flannigan et al., 2001). Upper-air circulation patterns have been related to area burned (Newark, 1975). Catastrophic burning events are related to the breakdown of the 500 mb long-wave ridge

(Nimchuk, 1983). Breakdown of these ridges generally occur at the same time as documented increases in lightning strikes and strong surface winds.

Regional and global links (teleconnections) between meteorological variables and weather anomalies have been identified. The most documented sources of teleconnections are the El Niño–Southern Oscillation and the Pacific Decadal Oscillation (section 2.2.2.2). Several North American studies have linked teleconnections to area-burned anomalies (Flannigan et al., 2000; Johnson and Wowchuk, 1993; Swetnam and Betancourt, 1990). Teleconnections may offer long-range forecasting techniques for temperature and precipitation anomalies that fire managers could use in estimating fuel moisture and fire potential (Flannigan et al., 2001). Winter sea surface temperatures in the Pacific are significantly correlated with warm-season temperature and seasonal area burned in Canada (Flannigan et al., 2000). Significant correlations between these factors vary by provincial region and phase of the North Pacific Oscillation (1953–1976 versus 1977–1995). Interestingly, the sign of the correlation changed from strongly negative (1953–1976) to strongly positive (1977–1995) for four regions (Alberta, western Ontario, eastern Ontario, and Quebec) at the same time they changed from strongly positive to strongly negative for two regions (British Columbia and Saskatchewan). During the same period, two regions did not change sign (Yukon/Northwest Territories and Manitoba). These shifts occurred at previously identified changes in climate regimes (e.g., section 14.6.2, Fig. 14.15), and emphasize the control the overall atmospheric circulation has on fire at a regional scale in understandable, but varying ways.

There are two different scenarios of the relay floristics (rate of spread of vegetation; *sensu* Egler, 1954) pathway for secondary succession after fire that operate in the boreal forest. The first is the process in which deciduous shrubs and trees initially colonize burned sites, but are replaced in the overstory in approximately 150 to 200 years by coniferous trees that may be limited in movement by the time necessary for successive generations to reach reproductive maturity or the presence of individual surviving trees dispersed throughout the burn. The second process is self-replacement, which occurs after fires by root sprouting (i.e., aspen, birch, balsam poplar (*Populus balsamifera*), and numerous shrub species) or by fire-stimulated seed release (i.e., black spruce) (Greene et al., 1999; Mann D. and Plug, 1999). Both of these successional processes occur in the boreal forest. However, the relative importance of each pathway in determining the structure of the boreal forest at a landscape scale is still unknown.

The fire regime describes the general characteristics of fire and its effects on ecosystems over time. It can be defined by specific components such as frequency, intensity, severity, size, and timing. These characteristics have been used to develop classification systems that aim to describe the principal types of fire regimes associated with different ecosystems. These fire/ecosystem regime categories are general and broad due to the large spatial and temporal variability exhibited by specific ecosystems (Whelan, 1995), but they do provide a conceptual model useful for understanding both fire behavior and fire effects in a particular system. Documentation of the components of fire regimes (i.e., ignition sources, frequency, extent, and severity) for specific ecosystems and geographic regions is also highly variable, and in many cases not well quantified.

Lightning strikes and humans are the two sources of ignitions in the boreal forest. Lightning is the most significant cause of fires (defined by total area burned), although this trend varies among regions. The number of lightning-caused fires generally declines as latitude increases because of decreased heating at the ground surface necessary to produce convective storms, and as climate becomes more maritime (cool layer at ground surface) (Johnson, 1992). Humans are responsible for high numbers of ignitions, but the fires started consume much less area because usually they are actively suppressed. Indigenous peoples ignited fires for specific purposes throughout history, but their impact on past overall fire regimes remains uncertain (Johnson, 1992; Swetnam et al., 1999). Specific regions of the boreal forest in North America experienced substantial anthropogenic fire impacts during the "gold rush" era of the late 19th and early 20th centuries.

14.9.2. Regional fire regimes

14.9.2.1. Russia

Fire statistics for the Russian Federation in general, and the Russian boreal region specifically, are incomplete at best (FAO, 2001; Stocks, 1991). Official fire statistics have been reported only for protected regions of Forest Fund land (section 14.3.1). Furthermore, only 60% of the Forest Fund land is identified as protected (FAO, 2001). Approximately 430 million ha of forested tundra and middle taiga in Siberia and the Far East receive no fire protection. The paucity of reliable statistics is a result of numerous issues including remoteness, lack of detection and mapping technology, lack of fire-management funding, and deliberate falsification of past records for political reasons. Humans were identified as the major source of ignitions at 65%, followed by lightning (16%), prescribed agricultural burning (7%), and other/unknown activities (12%) (Shetinsky, 1994). Intensive prevention and education programs have had little success in decreasing anthropogenic fires. Many of these fires grow to large sizes due to overstretched suppression resources.

Keeping these limitations in mind, the statistics for the protected Forest Fund area provide some perspective on fire across the Russian Federation. Between 18 000

and 37000 forest fires were detected annually from 1950 to 1999. The average annual area burned within the zone of detection for the decades 1950 to 1959, 1960 to 1969, 1970 to 1979, 1980 to 1989, and 1990 to 1999 was 1.54, 0.68, 0.48, 0.54, and 1.2 million ha, respectively (FAO, 2001). Indirect estimates of annual area burned in both protected and unprotected Forest Fund areas have been developed through modeling techniques. Shvidenko and Goldammer (FAO, 2001) used a modified expert system model (Shvidenko and Nilsson, 2000), available fire statistics, and forest inventory data on age and stand structure to calculate an estimated total of the annual average area burned in all of Russia over the past 30 years. The estimate applies to the Forest Fund and State Land Reserve area. An estimated 5.10 million ha burned annually, of which 3.94 million ha were in the boreal bioclimatic zones of forest tundra–northern taiga, middle taiga, and southern taiga (see Fig. 14.1).

Satellite remote-sensing techniques provide insight into the potential total extent of area burned across major regions of the Russian Federation. In 1987, an estimated 14.4 million ha burned in the Russian Far East and eastern Siberia (Cahoon et al., 1994), and in 1992, an estimated 1.5 million ha burned in all of the Russian territories (Cahoon et al., 1996). In 1998, following a very strong El Niño, an estimated 9.4 million ha burned in the Asian regions of Russia (FAO, 2001).

Only a small fraction of total forested area falls under any organized fire-suppression management. Fire suppression is headed by the Ministry of Natural Resources of Russia, which manages suppression efforts through regional offices. Fire-suppression resources include both ground and aerial operations. Aerial operations provide detection and monitoring services, and direct suppression resources (i.e., water and retardant drops, transport of ground personnel and smokejumpers). The State Forest Guard (ground suppression) and the Avialesookhrana (aerial detection and suppression) coordinate fire suppression with local and regional authorities. Under severe fire conditions, military detachments and local populations are recruited.

Operational policy and logistical allocation follow fire danger predictions, which are based on weather and climatic conditions. The Nesterov fire index, similar to the Canadian Forest Fire Danger Rating System or the US National Fire Danger Rating System, is used for prediction. Aircraft patrols and resource deployments are based on the fire index predictions. A severe limitation to successful fire management has been a lack of funding – in 1998, only US$ 0.06 per hectare was allocated to fire suppression (FAO, 2001). In addition, a lack of advanced technology equipment (i.e., satellite monitoring, radios, etc.), aircraft, and State Forest Guard personnel, as well as unfavorable land-use practices, have been identified as major weaknesses in the current system.

14.9.2.2. Canada

Canadian fire management agencies developed a large-fire database for all fires larger than 200 ha for the period 1959 to the present (Stocks et al., 2000). Fires larger than 200 ha represent only 3.5% of the total number of fires, but 97% of the total area burned over this period (Stocks et al., 2000). The fire perimeters were digitized and mapped in a geographic information system, and the database includes ancillary information such as ignition location and date, size, cause, and suppression action(s) taken. This database has been expanded into the past where data exist (as far back as 1918), and is continuously updated with each passing fire season. Total area burned in Canada has more than doubled since the 1970s, and the upward trend is well explained by warmer temperatures (Gillett et al., 2004).

Lightning-caused fires predominate throughout the fire record and account for almost all large fires in the northern portions of Canada. From 1959 to 1997, lightning ignited approximately 68% of all fires, and those fires accounted for approximately 79% of the total area burned (Stocks et al., 2000). Temporal trends show a steady increase in the number of lightning fires and their contribution to total area burned from the 1960s through the 1990s, which fire managers attribute to technology improvements in fire detection and monitoring. Anthropogenic fires are a significant contributor to the total number of fires almost exclusively in populated areas and along the road network, and suppression of these fires is effective in limiting the total area burned. Temporal trends show a steady decrease in total area burned due to anthropogenic ignitions, attributed to aggressive fire suppression tactics.

The average annual area burned between 1959 and 1997 was approximately 1.9 million ha, with interannual variability ranging from 270000 to 7.5 million ha burned (Stocks et al., 2000). Spatial trends identified a few ecozones (taiga plains, taiga shield, boreal shield, and boreal plains; see Wiken, 1986 for definitions) that accounted for the majority (88%) of total area burned between 1959 and 1997, primarily because these ecozones have a continental climate that is conducive to extreme fire danger conditions and have large uninhabited areas with low values-at-risk, so fires are allowed to burn unimpeded (Stocks et al., 2000).

Organized fire suppression and management has operated in Canada since the early 1900s, initiated as a response to large catastrophic fires, much like those experienced in the United States. Canada is recognized worldwide for its advanced technologies and operational efficiencies in both fire prevention and suppression. The Canadian Forest Fire Danger Rating System (CFFDRS) was first developed in 1968 and consists of two subcomponents: the Canadian Forest Fire Weather Index (FWI) system, which provides a quantitative rating of relative fire potential for standard fuel types based upon weather observations; and the Canadian

Forest Fire Behavior Prediction system, which accounts for fire behavior variability of fuel types based on topography and components of the FWI. The CFFDRS is used for training, prevention, operational planning, prescribed burning, and suppression tactics. In addition, researchers use CFFDRS for investigating fire growth modeling, fire regimes, and potential climate change impacts. The system is used extensively in Alaska in place of the US Fire Danger Rating System – a system developed primarily for the lower 48 states.

Aerial reconnaissance in conjunction with lightning detection systems has been employed heavily since the 1970s throughout the North American boreal forest (including Alaska). The lightning detection system identifies areas of high lightning strike density and allows for focused aerial detection operations. This has greatly increased detection efficiencies over remote regions.

14.9.2.3. United States (Alaska)

The fire record for the Alaskan boreal forest has evolved over time and consists of three datasets (Kasischke et al., in press). The first is a tabular summary of total annual area burned since 1940. The second is a tabular database that contains the location, ignition source, size, management option, and initiation and extinguishment date for all fires since 1956. The third is a geographic information system database of the boundary of fires since 1950. The spatial database includes all fires larger than 400 ha occurring from 1950 to 1987, and all fires larger than 25 ha occurring since 1988.

Early studies minimized the importance of lightning as an ignition source in the Alaskan boreal forest because anthropogenic ignitions were thought to be more important (Lutz, 1956). However, the implementation of digital electronic lightning detection systems along with a more thorough review of fire statistics led to the realization that lightning is not only widespread throughout the growing season in Interior Alaska, but is responsible for igniting the fires that burn most of the area (Barney and Stocks, 1983; Gabriel and Tande, 1983). Analysis of fire statistics from the Alaska Fire Service shows that while humans start more than 61% of all fires, these fires are responsible for only 10% of the total area burned (Kasischke et al., in press). The remaining fires are the result of lightning ignitions.

Convective storms and associated lightning can range in size from individual clouds to synoptic thunderstorms covering thousands of square kilometers. A single thunderstorm may produce most of the annual lightning strikes in an area (Nash and Johnson, 1996). In Interior Alaska, the lightning density gradient generally runs from high in the east to low in the west, parallel with the warmer summer climate in the interior continental areas and cooler maritime summer climate near the coast (Kasischke et al., in press). However, mapped fires that originate from lightning strikes are well distributed throughout the interior of the state. In contrast to light-ning ignitions that are uniformly distributed between the Brooks and Alaska Ranges, anthropogenic fire ignitions are centered around major population centers (Fairbanks and Anchorage), as well as along the major road networks (Kasischke et al., in press).

The presence of the boreal forest landscape may promote convective thunderstorms. In central Alaska, the density of lightning strikes is consistently highest within boreal forest compared to tundra and shrub zones across a climatic gradient (Dissing and Verbyla, 2003). Within the tundra, the number of lightning strikes increases closer to the boreal forest edge. The paleo fire record indicates that wildfires increased once black spruce became established in Interior Alaska (despite a cooler, moister climate). This may have been due to two factors: 1) increased landscape heterogeneity and higher sensible heat fluxes (see section 14.2.5 BOREAS results) leading to increased convective thunderstorms; and 2) increased fuel flammability associated with the black spruce vegetation type (Chambers and Chapin, 2003; Dissing and Verblya, 2003; Kasischke et al., in press; Lynch et al., 2003). These results suggest that climate changes that promote the expansion or increase in density of conifer forest are likely to increase the incidence of fire, but that climate changes that decrease conifers (too-frequent burning, aridification) are likely to decrease subsequent burning.

The annual area burned in Alaska exhibits a bimodal distribution, with years of high fire activity (ignitions and area burned) punctuating a greater number of years of low activity. For the Alaskan boreal forest region, 55% of the total area burned between 1961 and 2000 occurred in just 6 years. The average annual area burned during these episodic fire years was seven times greater than the area burned in the low fire years.

With the observed increase in air temperature and lengthening of the growing season over the past several decades in the North American boreal forest region, a corresponding increase in fire activity between the 1960s and 1990s might be expected (Stocks, 2001). For the Alaskan boreal forest region (which was less affected by fire suppression efforts than southern boreal areas), such an increase in fire activity was not apparent until the summer of 2004, in which a record 2.71 million ha burned. That summer (May–August) also had the highest mean monthly temperatures recorded at Fairbanks since observations began in 1906. A record 1.84 million ha also burned in 2004 in the adjacent Yukon Territory, amounting to about 12.4% of all forest land in the Yukon. Between 1981 and 2000 there was only a slight (7%) rise in the annual area burned (297 624 ha/yr) compared to the period between 1961 and 1980 (276 624 ha/yr) (Kasischke et al., in press). These extensive 2004 fires have clearly established a significant upward trend in the area burned during the period of record. The frequency of large fire years has been greater since 1980 (five large fire years) than before 1980 (two large fire years), and the increase in average

annual area burned between these periods is due to the increase in frequency of large fire years and the decrease in fire-fighting activities in remote areas. The fire data record for Alaska is consistent with an increase in large fires in response to recent climate warming, but not sufficient to determine definitively whether the increase is outside the range of natural variability. The official fire statistics for Alaska show that there were two large fire years per decade in the 1940s and 1950s, indicating that the frequency of large fire years has been relatively constant over the past 60 years, although this entire period is distinctly warmer than preceding centuries.

The number and size distribution of fires in the Alaskan boreal forest region is different during low and severe fire years. During low fire years between 1950 and 1999, an average of 17 fires greater than 400 ha occurred per year, with an average size of 7800 ha. In contrast, during high fire years an average of 66 fires greater than 400 ha occurred, with an average size of 20 300 ha (Kasischke et al., in press). In low fire years, 73% of the total area burned occurred in fires larger than 50 000 ha. In high fire years, 65% of the total area burned occurred in fires larger than 50 000 ha. In low fire years, 9% of the total area burned in fires larger than 100 000 ha, with no fires larger than 200 000 ha. In contrast, during high fire years, 33% of the total area burned in fires larger than 100 000 ha.

Fire managers in Alaska typically recognize two fire seasons (Kasischke et al., in press). The major fire season typically occurs after mid-June when the surface of the earth becomes warm enough to drive convective thunderstorm activity. However, there is an earlier fire season throughout the state associated with the extremely dry fuel conditions that occur immediately after snow-melt and before leaf-out in late spring. At this time, precipitation levels are low, and fuel moisture conditions are extremely low because of the curing of dead vegetation during winter and the lack of green vegetation. During this period, human activities result in the majority of fire ignitions.

Fire management and suppression is a relatively new concept in Alaska and did not become an organized effort until 1939. In the early 1980s, fire-management efforts in Alaska were coordinated under the direction of an interagency team. Beginning in 1984, fire-management plans were developed for thirteen planning areas. The fire plans provide for five separate suppression options:

- *Critical protection* is provided for areas of human habitation or development. These areas receive immediate initial attack and continuing suppression action until the fire is extinguished.
- *Full protection* is provided for areas of high resource values. Fires receive immediate initial attack and aggressive suppression to minimize area burned.
- *Modified action* provides for initial attack of new fires during the severe part of the fire season (May 1–July 10). Escaped fires are evaluated by the land manager and suppression agency for appropriate suppression strategies. On specified dates (generally after July 10), the modified action areas convert to limited action.
- *Limited action* is provided for areas of low resource values or where fire may actually serve to further land management objectives. Suppression responses include the monitoring of fire behavior and those actions necessary to ensure it does not move into areas of higher values.
- *Unplanned areas* exist where land managers declined participation in the planning process. These few unplanned areas receive the equivalent of full protection.

The formation of these plans radically changed wildland fire management in Alaska. The adoption of these cooperative plans created areas where fires were no longer aggressively attacked due to the low economic resource value of those lands. The primary goals of the plans are to restore the natural fire regime to the boreal forest ecosystem and to reduce suppression costs.

14.9.2.4. Fennoscandia

Finland, Sweden, and Norway account for a very small percentage of total area burned in the boreal forest and generally have not experienced large fires in modern times. This can be attributed to the ease of access throughout these relatively small countries and their highly managed forest systems. In addition, lightning fires are not a major factor, accounting for less than 10% of all fires (Stocks, 1991). Fire statistics for this region of the boreal forest are limited and discontinuous. The lack of natural fire is one of the principal causes of endangerment of a set of fire-dependent species in northern Fennoscandia (Essen et al., 1992).

Finland reported an annual average of 800 ha burned during the 1990s (FAO, 2001). Since record keeping began in 1952, there has been a steady decrease in average annual area burned from a high of 5760 ha in the 1950s to 1355 ha in the 1960s to less than 1000 ha from 1971 to 1997 (FAO, 2001). An average of 2224 fires per year occurred during the period 1995 to 1999. Anthropogenic fires accounted for 61% of all fires, followed by 29% of unknown cause, and 10% caused by lightning (FAO, 2001).

Boreal forest covers most of Sweden and includes a mix of flammable conifer trees, shrubs, and mosses. Sweden reported an annual average of 1600 ha burned during the 1990s (FAO, 2001). Humans are the major cause of fires accounting for approximately 65% (FAO, 2001) of the annual average of 3280 fires during the 1990s (FAO, 2001). Norway reported an average of 564 ha burned annually between 1986 and 1996 (FAO, 2001). The highest frequency of fires occurs in the boreal forest region of the eastern lowlands (Mysterud et al., 1998). On average, there were only 513 fires per year in Norway during the 1990s (FAO, 2001).

Forest fires are virtually absent from the sparsely forested regions of Iceland and Greenland. No fire statistics were reported to the FAO for the period 1990 to 1999.

14.9.3. Possible impacts of climate change on fire

Rupp et al. (2000a,b) used a spatially explicit model to simulate the transient response of subarctic vegetation to climatic warming in northwestern Alaska near treeline. In the model simulations, a warming climate led to more and larger fires. Vegetation and fire regime continued to change for centuries in direct response to a 2 to 4 °C increase in mean growing-season temperature. Flammability increased rapidly in direct response to temperature increases and more gradually in response to simulated climate-induced vegetation change. In the simulations, warming caused as much as a 228% increase in the total area burned per decade, which led to a landscape dominated by an increasingly early successional and more homogenous deciduous forest.

Turner M. et al. (2003) used the same model (Rupp et al., 2000b) to simulate fire-regime sensitivity to precipitation trends. Precipitation projections from global climate models have the largest associated errors and the highest variability between models. A simulated instantaneous 2 °C increase in average growing-season temperature was applied with two different precipitation regimes (a 20% increase and a 20% decrease from current precipitation levels) to explore the possible influence of climate change on long-term boreal forest ecosystem dynamics. Both scenarios projected an increase in the total number of fires compared to current climate. However, the distribution of fire sizes was surprising. As expected, the warmer and drier scenario resulted in fewer small fires and an associated shift toward larger fires. Also as expected, the warmer and wetter scenario resulted in fewer large fires and an associated shift toward smaller fires. However, the distribution of very large fires (burning >25% of the total landscape area) was unexpected. The warmer and wetter scenario produced more very large fires compared to the warmer and dryer scenario. The warmer and dryer climate scenario experienced frequent medium-sized fires, which prevented fuels from building up across the landscape and limited the number of large fires. In contrast, the warmer and wetter climate scenario led to frequent small fires, which allowed the development of well-connected, highly flammable late-successional stands across the landscape.

Additional model simulations suggest that vegetation effects are likely to cause significant changes in the fire regime in Interior Alaska (Rupp et al., 2002). Landscapes with a black spruce component were projected to have more fires and more area burned than landscapes with no black spruce component. Black spruce landscapes were also projected to experience numerous fires consuming extensive portions (more than 40%) of the landscape. These results agree with observations in the Canadian boreal forest where 2% of the fires account for

98% of the total area burned (Stocks, 1991). Large-scale fire events need to be realistically represented in ecosystem models because they strongly influence ecosystem processes at landscape and regional scales. These results have strong implications for global-scale models of terrestrial ecosystems. Currently, these models consider only plant functional types distinguished by their physiological (C_3 versus C_4 photosynthesis), phenological (deciduous versus evergreen), and physiognomic (grass versus tree) attributes. The fire-modeling results suggest the need for a finer resolution of vegetation structure and composition related to flammability in order to simulate accurately the dynamics of the fire regime, and to understand how different climate changes are likely to change ecosystems at several different scales.

Modeling results show that fire regime plays an important role in determining the overall relative abundance of ecosystem types at any given time, and that different fire regimes create qualitatively different patterns of ecosystem placement across the landscape (Rupp et al., 2000b, 2002). One process is "contagion" or the spread of effects into one type largely due to its juxtaposition with another. Simulation results in a typical Alaska black spruce landscape projected increases in the total amount of deciduous forest that burned in two landscapes that contained a black spruce component. The results indicated a much shorter fire return interval for deciduous forest in a landscape dominated by black spruce, and the fire return times were similar to actual fire intervals calculated by Yarie (1981) for deciduous forest in Interior Alaska (Rupp et al., 2000b, 2002). Landscape-level changes in the fire return interval of specific fuel types is an important effect of spatial contagion that currently cannot be addressed by statistical formulation within a global vegetation model. Although there is an excellent quantitative understanding of fire behavior as a function of climate/weather and vegetation at the scale of hours and meters (Johnson, 1992), the dynamic simulation of fire effects at landscape or regional scales remains rudimentary (Gardner et al., 1999). A long-term potential consequence of intensified fire regimes under increasing temperatures is that fire-induced changes in vegetation are likely to lead to a more homogenous landscape dominated by early-successional deciduous forest (Rupp et al., 2000b, 2002). This has significant implications for the regional carbon budget and feedbacks to climate (section 14.10.2). A shift from coniferous to deciduous forest dominance is very likely to have a negative feedback to temperature increases due to changes in albedo and energy partitioning (Chapin et al., 2000).

Stocks et al. (1998) used outputs from four GCMs to project forest-fire danger in Canada and Russia in a warmer climate. Temperature and precipitation anomalies between runs forced with current atmospheric CO_2 concentrations and those forced with doubled atmospheric CO_2 concentrations were combined with observed weather data for 1980 to 1989 in both Canada

and Russia. All four models projected large increases in the areal extent of extreme fire danger in both countries under the doubled CO_2 scenarios. A monthly analysis identified an earlier start date to the fire seasons in both countries and significant increases in total area experiencing extreme fire danger throughout the warmest months of June and July. Scenarios are still of limited use, however, in projecting changes in ignitions.

Model projections of the spatial and temporal dynamics of a boreal forest under climate change were made for the Kas-Yenisey erosion plain in the southern taiga of western Siberia (Ter-Mikaelian et al., 1991). This study projected that the number of years in which there are severe fires would more than double under a summer temperature increase from 9.8 to 15.3 °C, the area of forests burned annually would increase by 146%, and average stored wood mass would decrease by 10%.

Flannigan and Van Wagner (1991) also investigated the impact of climate change on the severity of the forest fire season in Canada. They used projections from three GCMs forced with doubled atmospheric CO_2 concentrations to calculate the seasonal severity rating across Canada. Their results suggest a 46% increase in seasonal severity rating, with a possible similar increase in area burned, in a doubled CO_2 climate.

Flannigan et al. (1998) looked at future projections of wildfire in circumpolar boreal forests in response to scenarios of climate change. Simulations were based on GCM outputs for doubled atmospheric CO_2 concentrations. The simulation and fire history results suggested that the impact of climate change on northern forests as a result of forest fires may not be severe as previously suggested, and that there may be large regions of the Northern Hemisphere with a reduced fire frequency. These simulation results are attributed to a switch from using monthly to using daily GCM output. The scenarios still produced areas where the interval between fires is likely to decrease (i.e., more frequent fires), but they also produced regions of no change or with greater probability of an increasing interval (i.e., less frequent fires).

14.10. Climate change in relation to carbon uptake and carbon storage

14.10.1. The role of the boreal forest in the global carbon cycle

Within the terrestrial biosphere, forests cover 43% of the land area but are potentially responsible for 72% of the annual net primary productivity (McGuire et al., 1995b). The boreal forest covers roughly 1.37 billion ha and by itself (not including high-latitude tundra) contains approximately 20% of global reactive soil carbon, an amount similar to that held in the atmosphere (IPCC, 2001; Schlesinger, 1997). Climate change can affect high-latitude carbon cycling at multiple timescales. The most likely mechanism for significant short-term change

in boreal carbon cycling resulting from climate change is a change in rates of organic matter decomposition in the forest floor and mineral soil resulting from major changes in species composition caused by alteration of disturbance regimes. Climate change can also strongly affect rates of carbon cycling through its control of the disturbance regime and the subsequent successional development of ecosystems (Barr et al., 2002; Gower et al., 2001; Jiang et al., 2002; Trumbore and Harden, 1997; Wang et al., 2001; Zimov et al., 1999). Climate-induced shifts in dominant tree species composition within the present boreal forest (Carcaillet et al., 2001; Hogg and Hurdle, 1995; Smith T. et al., 1992) are likely to have profound impacts on the global carbon budget (Gower et al., 2001; Kasischke et al., 2002).

Boreal and subarctic peatlands contain approximately 455 Pg of carbon accumulating at an average rate of 0.096 Pg/yr, and constitute a significant proportion of the total boreal carbon pool (Gorham, 1991). The majority of peat consists of molecules that are highly resistant to degradation (e.g., lignin and cellulose). Species composition in sphagnum bogs is highly resilient (likely to remain the same or recover after change) because the mosses modify the local environment to produce highly acidic conditions, and their resiliency increases with age (Kuhry, 1994).

14.10.2. The role of disturbance in the carbon cycle of the boreal forest

Four processes largely control the storage and release of carbon in boreal forests: the rate of plant growth; the rate of decomposition of dead organic matter; the rate of permafrost accretion and degradation; and the frequency and severity of fires (Kasischke et al., 1995). All four processes are affected by landscape-scale disturbance. Differences in carbon cycling between mature and recently disturbed forest ecosystems have been observed in both experimental studies and modeling experiments. Some studies (Arain et al., 2002; Valentini et al., 2000) suggest that the annual carbon budget of the mature northern forest is at equilibrium and in some cases losing carbon to the atmosphere. In addition, model results and field experiments show that when ecosystems are disturbed, significant losses of soil carbon and nutrients can occur (Schimel et al., 1994) for a number of years after the disturbance.

The effects of temperature and disturbance (i.e., fire and grazing) on carbon exchange over three years in five undisturbed sites and five disturbed sites in forests of northeast Siberia were measured by Zimov et al. (1999) and results show that disturbance increased the seasonal amplitude of net carbon exchange. Disturbance had a larger effect on seasonal amplitude than either interannual or geographic differences in growing season temperature.

Fire affects the storage of carbon in the boreal forest in at least five ways: it releases carbon to the atmosphere;

converts relatively decomposable plant material into stable charcoal; re-initiates succession and changes the ratio of forest-stand age classes and age distribution; alters the thermal and moisture regime of the mineral soil and remaining organic matter, which strongly affects rates of decomposition; and increases the availability of soil nutrients through conversion of plant biomass to ash (Kasischke et al., 1995). Each of these effects exerts an influence at different timescales. As a result, the effect of a given climate scenario on carbon storage in the boreal region will be greatly influenced by fire regime (section 14.9), and represents a complex calculation requiring a great deal of specific spatial and temporal information.

Relatively few studies have directly examined carbon emissions in the boreal forest resulting from fire. Nonetheless, valuable contributions have been made by studies that used remotely sensed data to estimate direct carbon emissions from combustion as fires are occurring (Amiro et al., 2001; Isaev et al., 2002). These studies show that wildland fires have the potential to release a significant amount of carbon directly into the atmosphere. The effects of wildfire on this initial carbon loss are highly variable and strongly influenced by forest type and fire severity (Wang et al., 2001). Soil drainage (defined by the water table, moss cover, and permafrost dynamics) is the dominant control of direct fire emissions (Harden et al., 2000).

Fires cause the release of carbon not only during but also for a short time after fires. Tree mortality after surface fires can be extensive, leading to a pulse of carbon released from heterotrophic respiration as fine roots die and aboveground fine fuels (i.e., needles) fall to the ground and decompose rapidly (Conard and Ivanova, 1997). The non-combustion post-fire release of CO_2 has the potential to affect global levels of atmospheric CO_2 over the short term, representing another mechanism by which the boreal forest can play a significant role in the global carbon cycle. Together, these direct and indirect fire-generated carbon emissions from boreal forests worldwide may exceed 20% of the estimated global emissions from all biomass burning (Conard and Ivanova, 1997).

Wildland fires change the distribution of soil organic carbon pools with respect to their turnover (release to CO_2) times. Soil carbon in the form of forest litter that has fallen recently has a relatively rapid turnover rate, but carbon in the form of charcoal is stable (very long turnover rates). If rates of burning increase in the boreal forest, an increasing proportion of soil organic carbon is likely to be converted to stable charcoal. This change in the soil organic carbon pool allocation is difficult to estimate, because forest type and fire severity strongly influence the effects of wildfire on carbon redistribution (Wang et al., 2001). Harden et al. (2000) show the importance of this shifting distribution of turnover times in soil organic carbon. They developed a system of ordinary differential equations to explore constraints on carbon losses to fire,

using modern estimates of carbon production, decomposition, and storage; a model of fire dynamics developed for millennial timescales; and an assessment of the long-term carbon balance of a variety of boreal landscapes in North America. A sensitivity analysis found that their model results were responsive to the rate at which charred plant remains decomposed. Unfortunately, the specific characteristics of fires that result in maximum charcoal production are not well studied. However, it seems reasonable to infer that a moderate-intensity fire, in which combustion is enough to kill trees but not intense enough to consume them completely, would produce the greatest amount of charcoal. In complex mountainous or hilly terrain at high latitudes, north-facing slopes have higher fuel moisture content and as a result generally experience less complete combustion of fuels during fire (Van Cleve et al., 1991). This suggests that slope aspect might be an important factor in the conversion of plant biomass to charcoal.

Much of the difference in carbon cycling after disturbance can be linked to shifts in species composition and ecosystem age structure that enhance both peak summer CO_2 uptake and winter CO_2 efflux. The seasonal amplitude of net ecosystem carbon exchange in northern Siberian ecosystems is greater in disturbed than undisturbed sites, due to increased summer influx and winter efflux (Zimov et al., 1999). Disturbed sites differ from undisturbed sites during the summer, having 2.1 to 2.5 times the daytime CO_2 influx and 1.8 to 2.6 times the nighttime CO_2 efflux. Winter respiration in disturbed sites is 1.7 to 4.9 times that in undisturbed sites. Carbon cycling within disturbed ecosystems is more sensitive to interannual temperature variability than older forests, and disturbed sites also experience a greater difference in annual carbon exchange with the atmosphere in warm versus cold years than older forests (Zimov et al., 1999).

Two hypotheses have been advanced to explain why these differences in carbon cycling caused by enhanced CO_2 summer uptake and winter efflux occur in disturbed areas. One hypothesis is that the recent increase in March and April temperatures in high-latitude continental regions of North America and Siberia has advanced snowmelt and lengthened the growing season (section 6.4). The second hypothesis is that temperature-driven increases in summer carbon gain (greater CO_2 uptake from greater growth) balanced by increased winter respiration (greater CO_2 release from enhanced decomposition and live respiration) could enhance the seasonal amplitude of atmospheric CO_2 concentrations without a change in net annual carbon accumulation. Although the mechanism remains somewhat uncertain, experimental studies confirm that these responses do occur under appropriate conditions.

14.10.3. Climate and carbon allocation in the boreal forest

Changes in species composition modify the way carbon is allocated and stored. Deciduous forests experience

greater carbon cycling (production and decomposition) than coniferous stands (Gower et al., 2001). Both aboveground net primary production and overall (including belowground) net primary production were roughly two times greater in a boreal deciduous forest than a coniferous forest. The fraction of net primary production allocated to coarse- and fine-root primary production is roughly two times greater for evergreen conifers than deciduous trees (Gower et al., 2001). Because of these differential allocation patterns between deciduous and evergreen stands, the amount of carbon in the soil of mature black spruce stands is approximately three times the amount of carbon in the biomass of the trees (Kasischke et al., 1995). Since the rate of decomposition is higher in deciduous than in coniferous forests (because of both litter quality and site conditions), nitrogen is probably more available in deciduous forests, further increasing production (Makipaa et al., 1999). These results make sense physiologically, since deciduous species have higher maximum rates of photosynthesis and productivity than evergreens and produce litter that quickly decomposes.

Aboveground carbon pools are directly related to stand age. Gower et al. (2001) found that the effect of stand age (young versus old stands) on net primary production is roughly equivalent to the effect of soils (fertile versus infertile) and annual variation in the environment (favorable versus unfavorable weather). Similarly, Wang et al. (2001) found that wildfire exerts a lingering effect on carbon exchange between the boreal forest and the atmosphere via its effect on the age structure of forests and leaf-area index (LAI) during succession. They also found a strong inverse linear relationship between aboveground net primary productivity and age that was largely explained by a decline in LAI. Modeling results from Kurz and Apps (1999) suggested that forest ecosystems in Canada were a carbon sink from 1920 to 1980 and a source from 1980 to 1989. They suggested that this was a result of a change in the disturbance regime, and this finding is consistent with recent fire statistics (see section 14.9.2). Sometime around 1977, a regime shift in the climate of the North Pacific Ocean occurred that has been suggested to be part of a low-frequency oscillation (Niebauer, 1998). One of the consequences of this shift was that the position of the Aleutian Low associated with El Niño moved even farther eastward than it did in previous El Niño years. This shift is consistent with a more easterly (less southerly) flow component across Interior Alaska, which could exert teleconnective influences on the fire-dominated disturbance regime of Canada (Bonsal et al., 1993). If the key control over fire occurrence was a one-time climate regime shift caused by a change in sea surface temperature in the northeast Pacific Ocean, it suggests that climate changes occurring at low temporal frequencies exert a strong influence on the rate of carbon cycling in regions where the disturbance regime is climatically driven. Kurz and Apps (1999) suggested that as stand age increases, the ability to sequester carbon decreases and the susceptibility to disturbance increases.

Modification of soil thermal regime and permafrost degradation as a result of fire have been documented. Warmer and drier (due to reduced cover of saturated mosses) conditions following a forest fire increase decomposition and decrease carbon storage (Kasischke et al., 1995). Simulation results suggest that a 5 ºC increase in average annual air temperature results in a 6 to 20% decrease in the total carbon stored in the soil over a 25-year period (Bonan and Van Cleve, 1992). In China, Wang et al. (2001) found that soil-surface CO_2 flux decreases immediately after wildfire because of a lack of root respiration, which accounts for about 50% of total soil-surface flux. In the time after a fire during which appreciable tree mortality occurred, the majority of respiration shifts from autotrophic to heterotrophic. As a consequence of the increased heterotrophic respiration and low net primary production in the early stages of succession, areas that have recently burned in the boreal forest tend to act as a carbon source for a brief period of time. Rapalee et al. (1998) found evidence that fire scars on the landscape are a net carbon source for about 30 years after burning, after which systems become a net carbon sink. Experiments in the Alaskan boreal forest showed that about 20% of the carbon in the soil surface layer is lost through decomposition during the first 20 to 30 years after a fire due to increased soil temperature (Van Cleve and Viereck, 1983). Rapalee et al. (1998) asserted that ecosystem changes in net ecosystem production are driven by changes in decomposition and species composition. They further suggested that changes in species composition are driven by fire-induced modification of the active layer. The relative importance of active-layer modification depends to a large extent on aspect and fire severity.

Fire frequencies in the sphagnum peatlands have decreased over the past 7000 years due to cooler and wetter conditions (Kuhry, 1994). Carbon emissions from peat combustion are still an order of magnitude greater than warming-induced oxidation (Gorham, 1991). Fire affects not only the amount of carbon in the forested peat systems but also the subsequent rate of accumulation. Kuhry (1994) found that peat accumulation in sphagnum-dominated peatlands of western boreal Canada decreased significantly with increasing fire frequencies. It is estimated that warming and drying would result in relatively rapid decomposition of peat soil organic carbon (Schimel et al., 1994). Valentini et al. (2000) investigated two contrasting land cover types, a regenerating forest and a bog, in the central Siberian region during July 1996, and found that net CO_2 uptake was limited by the decreasing soil water content in the regenerating forest. Their results showed substantial differences in both transpiration and carbon assimilation. The bog used the incoming solar energy principally for transpiration and, because of the constant availability of water, transpiration was not sensitive to seasonal changes in moisture conditions. The bog system also maintained high carbon assimilation potential compared to the regenerating forest. This trend was

maintained and amplified in dry conditions, when the carbon uptake of regenerating forest decreased significantly. Bogs and peatlands represent a very different land cover type than forests and must be considered separately when assessing the role of disturbance in the boreal forest (see section 8.4.4.4).

14.10.4. Forest cover type, disturbance, and climate change

Vegetation response to climate change could feed back to cause large changes in regional and global climate through effects on terrestrial carbon storage (Smith T. and Shugart, 1993) and on water and energy exchange (Bonan et al., 1992; Chapin and Starfield, 1997). The rate and magnitude of this feedback is influenced by transient changes in the distribution of terrestrial ecosystems in response to changes in climate, disturbance regime, and recruitment rates. The long-term direction of ecosystem change is also sensitive to spatial patterns and processes operating at the landscape scale (Turner D. et al., 1995).

Current projections of vegetation response to climate change either assume that the disturbance regime does not change (Pastor and Post, 1986) or use globally averaged disturbance rates (Smith T. and Shugart, 1993). Conversely, projections of disturbance regimes in a warmer climate (Flannigan and Van Wagner, 1991; Flannigan et al., 1998; Kasischke et al., 1995) generally neglect rates and patterns of vegetation response to climate and disturbance. However, the climate–disturbance–vegetation interactions clearly influence the rate and pattern of changes in vegetation (Neilson, 1993; Noble, 1993) and disturbance (Gardner et al., 1996) through effects on fire probability and spread and pattern of colonization (Turner M. et al., 1997).

Landscape-scale interactions between vegetation and disturbance are particularly important in the forest–tundra ecotone (Chapin and Starfield, 1997; Noble, 1993; Starfield and Chapin, 1996) where vegetation change is very likely to have large feedbacks to climate (Pielke and Vidale, 1995). The potential colonization of tundra by forest is very likely to increase terrestrial carbon storage (Smith T. and Shugart, 1993), thereby reducing atmospheric carbon, but increase absorption of solar radiation (Bonan et al., 1992) thereby creating a positive feedback to regional temperature increases (Chapin and Starfield, 1997).

Modeling the transient dynamics of vegetation change allows investigation of both the short- and long-term responses of ecosystems to landscape-level disturbance and recruitment, and the subsequent feedbacks between climate and the biosphere. These spatial processes are responsible for long-term changes in vegetation distribution (Dale, 1997) in response to changing climate, and must eventually be incorporated into hemispheric- or global-scale spatio-temporal models of gradual climate change.

14.10.5. Land-use change

Atmospheric CO_2 and oxygen data confirm that the terrestrial biosphere was largely neutral with respect to net carbon exchange during the 1980s but became a net carbon sink in the 1990s (Schimel et al., 2001). However, the cause of this shift remains unclear. Several studies have indicated that land-use change is responsible for the majority of the terrestrial sink (Birdsey and Heath, 1995; Fang et al., 2001; Goodale et al., 2002; Houghton and Hackler, 2000; Houghton et al., 1983). Calculations of land-use changes can be used to calculate associated carbon fluxes (Houghton and Hackler, 2000). Since 1850, there has been a 20% decrease in global forest area, and during this period deforestation has been responsible for approximately 90% of the estimated emissions from land-use change (Houghton et al., 1999).

The majority of land-use change studies have focused on areas outside the boreal region, and a review of the critical issues provides perspective on the impact of land-use change on carbon cycling in the boreal forest. In the tropics, forests contain 20 to 50 times more carbon per unit area than agricultural land, and as a result, tropical deforestation during the early 1990s released 1.2 to 2.3 Pg of carbon annually (Melillo et al., 1996). Once tropical vegetation is cleared, soil mass is quickly lost through erosion and oxidation. When tropical forest soils are cleared of vegetation and cultivated, surface horizons experience exponential mass loss resulting in roughly a 25% decrease in carbon (Melillo et al., 1996). Despite the large atmospheric source of CO_2 from tropical deforestation, the terrestrial system is acting as a net sink for carbon (IPCC, 2001), and in a spatially explicit inversion analysis, Rayner et al. (1999) found no evidence of a large net source from the tropics. The spatial inversion analysis allows a more focused examination of carbon fluxes between discrete regions. For example, the lack of a large tropical net source suggests a tropical terrestrial sink of roughly the same magnitude. The exact nature of this tropical terrestrial sink remains a source of debate. Melillo et al. (1996) used gas flux studies to show that undisturbed tropical forests in the Brazilian Amazon are responsible for a net carbon uptake, but more work needs to be done to examine and quantify carbon flux from tropical forests experiencing and recovering from deforestation.

Like tropical forests, temperate and boreal regions in the Northern hemisphere have experienced substantial land-use changes in the past several hundred years. Siberian forests account for 20% of global forest area and net primary production; Valentini et al. (2000) estimated that approximately 800 000 ha are harvested there annually. Fang et al. (2001) found that Chinese forests acted as a carbon source from 1948 to 1980, and as a sink from 1981 to 1998. Subsequent works focused on constraining spatial and temporal aspects of carbon fluxes and therefore, several atmospheric inversion analyses have indicated a large terrestrial carbon sink in the Northern Hemisphere (Ciais et al., 1995; Fan et al., 1998; Keeling

et al., 1996; Rayner et al., 1999). Estimates of carbon flux in the United States derived from independent forest inventory methods (Birdsey and Heath, 1995; Caspersen et al., 2000; Turner D. et al., 1995) and ecosystem models (Hurtt et al., 2002) provide supporting evidence for the presence of a North American sink, although of a lower magnitude than that estimated by Fan et al. (1998). Goodale et al. (2002) found that growth rates in unmanaged forests of the eastern United States have changed little over the past several decades, suggesting that nearly all of the carbon accumulation in the region is due to forest regrowth from past disturbance rather than growth stimulated by increased atmospheric CO_2, nitrogen deposition, or climate change.

14.10.6. Nitrogen deposition and carbon dioxide fertilization

A process-based model that simulates the biomass production of Norway spruce in southeastern Norway under both current climate and climate change scenarios was used to project biomass production responses to three climate change scenarios (Zheng et al., 2002). Net primary production (dry mass) was projected to increase by 7% over the current 10.1 t/ha/yr under a mean annual air temperature elevated by 4 °C over present-day levels. Doubling current ambient CO_2 concentration was projected to increase net primary production by 36%. The scenario of both elevated temperature and elevated CO_2 concentration led to an increase in net primary production of nearly 50%, which was higher than the sum of the two effects alone.

Nitrogen availability is often the limiting factor in net primary productivity. The majority of anthropogenic nitrogen inputs come from combustion (both biomass and fossil fuel) and agricultural fertilizer application (IPCC, 2001). Photosynthetic rate is correlated with the nitrogen content of leaves, since carbon assimilation is driven by the nitrogen-rich enzyme rubisco. Hence, reduced nitrogen availability decreases both leaf nitrogen content and photosynthesis. As a result, the carbon and nitrogen cycles are fundamentally coupled. Due to this coupling, increased anthropogenic nitrogen deposition must be considered in conjunction with elevated CO_2 levels. Elevated CO_2 levels have multiple direct effects on fundamental biochemical processes such as photosynthesis and respiration, which collectively determine net primary production.

Among studies that manipulated both CO_2 and nitrogen availability, the mean enhancement of photosynthesis by elevated CO_2 levels at the lowest level of nitrogen availability was 40%, while the mean enhancement at higher levels of nitrogen availability was 59% (McGuire et al., 1995a). These results indicate that for a fixed increase in CO_2 concentration, biomass increases proportionally to increased nitrogen availability. In a review of the literature, McGuire et al. (1995a) also found that compared to low nitrogen availability and baseline CO_2 levels, increased nitrogen availability and elevated CO_2 concentrations significantly increased biomass accumulation, sometimes by a multiple of more than two. Differential increases in biomass in response to elevated CO_2 concentrations are found in different species: in general, deciduous species exhibit twice the growth response of conifer species to elevated CO_2 levels (Ceulemans and Mousseau, 1994).

The carbon and nitrogen cycles are also strongly correlated with evapotranspiration. Arain et al. (2002) examined the response of net ecosystem productivity and evaporation to elevated atmospheric CO_2 concentrations and found that modeled and measured results showed a linear relationship between CO_2 uptake and evaporation. This coupling implies that as nitrogen deposition increases and plant tissue carbon to nitrogen ratios decrease, nitrogen cycling increases at a fixed level of evapotranspiration (Schimel et al., 1997). This is essentially an example of biological supply and demand. It becomes less efficient for plants to exert energy on translocation before senescence; hence, the quality of litter increases. The scaling of this response from tissue to plant level is seen in the results of modeling and field studies showing that nitrogen fertilization results in increased net primary productivity (Bergh et al., 1999; Chapin et al., 1988; McGuire et al., 1992; Vitousek and Howarth, 1991).

At the ecosystem level, studies indicate that conifers and deciduous species differ in their response to elevated CO_2 levels. Arain et al. (2002) examined the response of boreal net ecosystem productivity to elevated CO_2 levels in both a 70-year-old aspen stand and a 115-year-old black spruce stand. They found that the aspen stand was a weak to moderate carbon sink while the black spruce stand was a weak carbon sink in cool years and a weak carbon source in warm years (consistent with Fig. 14.23 and the BOREAS results described in section 14.7.3.2). These results emphasize the practical importance of the strong coupling between water flux and both the carbon and nitrogen cycles. When midsummer temperatures were high, the net ecosystem production of the black spruce stand decreased significantly due to increased respiration. At longer timescales, reduced litter quality resulting from elevated CO_2 levels has the potential to cause long-term negative feedbacks that constrain the response of net primary productivity. Litter nitrogen concentration is generally positively correlated with decomposition rates, and Cotrufo et al. (1994) found that in deciduous stands, cumulative respiration rates were lower for litter derived from elevated CO_2 conditions while rates for Sitka spruce remained relatively unaffected. These results have implications for the response of forests not only to elevated atmospheric CO_2 concentrations but also to the warmer temperatures that are very likely to ultimately accompany elevated atmospheric CO_2 levels.

Schimel et al. (1994) found that the amount of nitrogen lost from an ecosystem is an increasing function of the rate at which nitrogen cycles through the system. For

example, nitrogen mineralization is a key index of soil inorganic nitrogen turnover, and is strongly correlated with evapotranspiration. Schimel et al. (1997) found evidence that losses of nitrogen trace gases are linked to the rate of mineralization of ammonium (NH_4) and nitrate (NO_3) from organic matter, a rate that increases as temperature and soil moisture increase. Similarly, the product of water flux and the ratio of NO_3 to dissolved organic nitrogen (DON) concentration directly control leaching losses of NO_3 and DON (Schimel et al., 1997). Hence, nitrogen losses are controlled by soil moisture and water flux. This linkage between hydrological and nutrient cycles is of critical importance in assessing the relevance of nitrogen mineralization enhanced by increasing temperature to net primary productivity. Schimel et al. (1997) noted that water, energy, and nutrient limitation of net primary productivity and carbon storage tend to equilibrate in near "steady-state" ecosystems. This implies that the greatest potential for discrepancies between carbon, nitrogen, and water cycling exist in recently disturbed ecosystems. In support of this, Schimel et al. (2001) noted that in general, carbon accumulation in recovering ecosystems is high and chronosequence studies show lower accumulation in undisturbed landscapes. The decreased net primary productivity observed in "mature" ecosystems is a consequence of the equilibration of the nitrogen and water fluxes. Hence, the impacts of temperature increases on enhanced nitrogen mineralization are likely to be greatest in recently disturbed ecosystems.

Finally, although it is not always the case that nitrogen limits growth, a review of studies exposing plants to both elevated CO_2 levels and increased soil nitrogen concentrations showed significant increases in net primary productivity (McGuire et al., 1995a). Under the assumption that "mature" ecosystems exhibit decreased net primary productivity because of equilibration of the nitrogen and water fluxes, elevated atmospheric CO_2 concentrations are likely to stimulate growth. The relatively rapid increase in atmospheric CO_2 concentrations makes this scenario even more plausible. Elevated atmospheric CO_2 concentrations have been shown to increase the amount of photosynthesis per unit of water transpired, also known as water-use efficiency. Schimel et al. (1994) suggested that if CO_2 or fertilizer and pollutant nitrogen increase global net primary production over the coming decades, it is possible for soil carbon increases to occur on a commensurate timescale. Despite this prospect of greater carbon storage, the estimated effect of increasing temperatures is sensitive to the feedback between primary production and decomposition via the nitrogen cycle. As soil organic matter is lost through enhanced nitrogen mineralization caused by temperature increases, more nitrogen becomes available for plant growth, which results in the formation of more soil organic matter, thus acting as a negative feedback (Schimel et al., 1994).

Another possible mechanism causing equilibration of the carbon, nitrogen, and water fluxes comes from examina-

tion of the tissue-level response to elevated atmospheric CO_2 concentrations. Acclimation to elevated CO_2 levels can occur through one or more of three processes of leaf-level carbon assimilation: carboxylation, light harvest, and carbohydrate synthesis (McGuire et al., 1995a). Under saturating light conditions at low levels of intercellular CO_2, assimilation is limited by the quantity and activity of rubisco, the enzyme that is primarily responsible for capturing atmospheric carbon in the production of sugars. At high levels of intercellular CO_2, the enzymatically controlled rate of carbohydrate synthesis, which affects the phosphate regeneration that is necessary for harvesting light energy, may regulate the fixation of carbon (McGuire et al., 1995a). Hence, mechanisms acting at scales from tissue-level biochemistry to ecosystem-level nutrient cycling exert influences to equilibrate carbon, nitrogen, and water fluxes in mature ecosystems. This equilibration has implications for recent patterns of carbon flux observed in terrestrial ecosystems. Schimel et al. (2001) noted that the terrestrial carbon sink must eventually become saturated because photosynthesis follows a saturating function with respect to CO_2. As the rate of photosynthesis slows, plant and microbial respiration must catch up eventually, reducing incremental carbon storage to zero. Simulations with the Terrestrial Ecosystem Model (Marine Biological Laboratory, Woods Hole) concur, suggesting that soon after atmospheric CO_2 concentration stabilizes, heterotrophic respiration comes into balance with net primary production and the CO_2-stimulated terrestrial carbon sink disappears (Melillo et al., 1996).

In addition to the effect that anthropogenic modification of carbon and nitrogen cycles has on atmospheric CO_2, temperature in boreal and tundra regions affects the intra-annual variability in atmospheric CO_2 concentrations. Surface temperature in the north is positively correlated with seasonal amplitude of atmospheric CO_2 the following year. Zimov et al. (1999) found that 75% of the annual increases in mean annual air temperature between 1974 and 1989 coincided with decreases in CO_2 amplitude at the Barrow monitoring station, consistent with observations of net summer CO_2 efflux from tundra and boreal forest during warm years.

14.11. Climate change and forest distribution

14.11.1. Historic examples of treeline movement

The contrast between the realm of life where trees dominate the environment and the very different realm where much shorter herbaceous and low woody vegetation is the exclusive plant cover is one of the most visually striking landscape characteristics of the circumpolar Arctic. A number of questions about arctic and associated alpine treelines have attracted scientific interest for well over a century. A simple catalog and summary of this body of research is too large for this chapter. Treeline questions have been studied from a number of

different perspectives, but nearly all are at least implicitly connected with the question of how cold temperatures limit tree growth and survival. Because of this overriding interest in temperature limits, and because of the ubiquitous occurrence of treelines across the Arctic and the high state of preservation of dead trees in the cold environment of the Arctic, treeline studies have much to offer on the specific question of climate warming and cooling. This section focuses on some recent studies that shed light on the long-term history of dynamics and movement of tree limits as related to specific temperature-controlled processes. These studies provide a perspective of long-term continuity, and insight into the mechanisms that recent temperature increases have affected and that warming projected by the ACIA-designated models could affect.

14.11.1.1. Northern Eurasia

Between 9000 and 7000 years BP, forest occupied what is now treeless tundra nearly to the arctic coastline throughout northern Russia (MacDonald et al., 2000). These results are based on earlier subfossil wood collections carried out by Russian scientists as well as modern collections of subfossil wood from the Kola, Yamal, and Taymir Peninsulas, and at the mouth of the Lena River. Subsequently, the greatest retreat of forest and expansion of tundra (compared to the modern position of the treeline) took place between 4000 and 3000 years BP. During the period of maximum forest advance, the mean July temperature in northern Russia (at the coast) was 2.5 to 7.0 °C higher than the present-day mean, based on modern tree growth relationships to temperature. The northward advance of the treeline reflected a series of other environmental changes in the Arctic, including increased solar insolation, reduced sea-ice cover in the Arctic Ocean, increased climate continentality, and a significant intrusion of warm North Atlantic water into the Arctic (MacDonald et al., 2000). This documented record of past forest advance suggests that there is a solid basis for projecting similar treeline change from scenarios that project similar temperature increases. It also suggests that the components of ecosystems present today have the capacity to respond and adjust to such climate fluctuations.

A reconstruction of treeline movement in the Swedish Scandes Mountains using 173 dated remains of pine wood reveals a that there has been a gradual decrease in the elevation of the treeline (with small fluctuations), generally consistent with climate cooling. Elevational decline in treeline as the result of decreasing temperatures began sometime after 10700 calendar years BP. Although the rate of treeline recession was greater before about 8000 years BP than after, generally the treeline evidence here indicates a smooth long-term temperature decrease with only a few minor, brief warming and cooling episodes. The total elevational retreat of treeline was estimated to be 500 m, corresponding to a temperature decrease of 6 to 8 °C. Since the beginning of the 20th century, however, a local

warming of about 1 °C has been associated with an upward movement of more than 100 m, which represents the largest adjustment of treeline position in the last 3000 years (Kullman, 2001).

14.11.1.2. Yamal Peninsula

Detailed analyses of the dynamics of polar treeline on the Yamal Peninsula are presented in Hantemirov (1999), Hantemirov and Shiyatov (1999, 2002), and Shiyatov et al. (1996). Holocene wood deposits in the southern Yamal Peninsula include a large quantity of subfossil tree remains, including stems, roots, and branches. This is the result of intensive accumulation and conservation of buried wood in permafrost. The existence of extensive frozen subfossil wood in the southern Yamal Peninsula in what is now the southern tundra zone was first noted and described by B.M. Zhitkov in 1912 during an ornithological expedition through the area. Tikhomirov (1941) showed that tree remains conserved in peat sediments were direct evidence that the northern treeline in the warmest period of the Holocene reached the central regions of the Yamal Peninsula (up to 70° N). Today the polar treeline is considerably further south on the Peninsula (67° 30' N).

Systematic collection of subfossil wood samples started in 1982 in the watersheds of the Khadyta, the Yadayakhodiyakha, and the Tanlova Rivers in the southern Yamal Peninsula, located between 67° 00' and 67° 50' N and 68° 30' and 71° 00' E. River flow in this area is from north to south, excluding the possibility that wood was transported to the collection site from more southerly locations; thus, there is very high confidence that the region experienced a considerably warmer summer climate in the relatively recent past.

Radiocarbon dating of the subfossil wood (53 dates) was cross dated with ring series from the samples, allowing the construction of a continuous tree-ring chronology 7314 years in length. Absolute dates can

Fig. 14.27. Dynamics of the polar treeline on the Yamal Peninsula in Siberia, showing the relative distance of sampled tree remains from the present position of northernmost open stands of larch in river valleys and the number of tree samples for each radiocarbon date. A proposed division of the Holocene into three stages based on climatic shifts is indicated (data from Hantemirov and Shiyatov, 1999).

generally be assigned to the recovered wood remains. The result makes it possible to reconstruct the dynamics of tree limits on the Yamal Peninsula during the Holocene (Fig. 14.27). From at least 10 000 to 9000 years BP, trees grew across most of the Peninsula. The most favorable conditions for tree growth (almost certainly warm summers) occurred from 7200 to 6000 BC. From about 6000 to 5600 BC, climatic conditions became less favorable for tree growth (almost certainly cooler summers), but trees persisted and did not retreat to the south. Beginning about 5400 BC, trees were displaced southward. The forest stand density also greatly decreased during this period, and it can be considered as a transition to the next stage of the Holocene. From 5400 until 1700 BC, the polar treeline was still located at 69° N, well north of the present-day position. In unfavorable periods (4500–3900 BC and 3600–3400 BC), tree survival was mainly restricted to the river corridors, but in climatically more favorable periods (5200–4500 BC, 3900–3600 BC, and 3400–1800 BC), forests grew on hills and raised surfaces beyond the rivers.

One of the most important periods of displacement of polar treeline to the south and major reduction in the density and productivity of forest stands occurred about 1700 BC. This stage can be regarded as the end of the Middle Holocene and the beginning of the modern stage of treeline evolution on the Yamal Peninsula. During the last 1700 years, forest–tundra and forest associations have been primarily restricted to river valleys in the southern part of the Peninsula. Somewhat more favorable conditions occurred from 1200 to 900 BC, from 100 BC to AD 200 and during the MWP (AD 700–1400).
Treeline dynamics for the last 4000 years of the Holocene were reconstructed with even greater precision using more than 500 cross-dated tree stems with known coordinates of their burial places in valleys of different rivers on the southern Yamal Peninsula (Fig. 14.28). Treeline displacements northward and southward were relatively small and less important during the last 3600 years than those that occurred in the previous few millennia. Treeline generally moved at the most 5 km to the south of the present-day treeline, and

subsequently northward only to the present boundary of open woodland in the river valleys. However, one particularly noteworthy major displacement of treeline to the south occurred during the second half of the 17th century BC. In this relatively short period (not exceeding 100 years), the boundary of larch open woodland moved southward nearly 15 to 20 km, and the treeline retreated a further 8 to 10 km during next 700 years. This major displacement of treeline in the 17th century BC appears to have been driven by strongly inclement climatic conditions (cold summers), representing the lowest reconstructed summer temperatures in the entire series. It was in the years immediately after 1657 BC that the temperature decreased sharply. Fourteen years during the interval 1630 to 1611 BC appear to have been extremely cold, reaching a nadir in two specific years, 1626 and 1625 BC. No other period during the reconstruction is even close. Moreover, it is clear that in 1625 BC, a severe freeze occurred in the middle of the summer (as indicated by characteristic anatomical structures of freeze injury in the tree rings). It is very probable that this short-term extreme climate event represented climate cooling following one of the largest volcanic eruptions of the last few millennia, which happened in about 1628 BC (possibly the eruption of the Santorini volcano in the eastern Mediterranean). The cooling appears to have reinforced another closely spaced cooling event that preceded it. The earlier of the two periods of extreme cold temperatures began sometime after 1657 BC, but in this case, it is difficult to determine the cause (Grudd et al., 2000). These events were the final circumstances that resulted in the most significant southward retreat of treeline during at least the last 4000 years. In spite of extremely favorable summer warmth that returned afterward and even persisted at various intervals, the treeline never returned to its previous boundary.

Another important result of dendrochronological dating of large samples of subfossil wood is the ability to calculate the relative abundance of Siberian spruce in forest stands of the area, which is an index or proxy for the degree of continentality of the climate. Figure 14.29 shows the change in the proportion of spruce in forest stands (the remaining part is all larch). In the first six centuries, from AD 900 to 1500, the proportion of spruce decreased from 22% to 3–5%. After that, the

Fig. 14.29. Change in the proportion of subfossil remains made up of spruce compared to larch in Yamal Peninsula samples (data from Shiyatov, 2003).

Table 14.8. Altitudinal displacement of the upper treeline in the Polar Ural Mountains during the last 1150 years (Shiyatov, 2003).

Period (AD)	Number of years	Change in treeline	
		Direction	Rate (m/decade)
850–1280	430	rise	1–2
1280–1580	300	retreat	2–3
1580–1790	210	rise	0.5–1.0
1790–1910	120	retreat	2–4
1910–2000	90	rise	4–6

percentage of spruce stabilized in the range of 7 to 10%. The 20th century is characterized by an increasing percentage of spruce in forest stands in the valley of the River Khadytayakha, and a weak northward advance of the polar treeline.

14.11.1.3. Polar Ural Mountains

Significant spatial and temporal changes took place in the upper treeline ecotone in the Polar Ural Mountains (66º–67º N, 65º–66º E) during the last millennium (Shiyatov, 1993, 1995, 2003). Within the treeline ecotone, located between 100 and 350 m above sea level, open forests of Siberian larch dominate. Patches of closed forests of mixed larch and Siberian spruce grow at lower altitudes in the ecotone. Up to the present, these forests have largely developed under conditions of very little human influence. A large number of wood remnants persist on the ground at elevations up to 60 to 80 m above the present treeline, and within the ecotone between forest and tundra. These wood remains have been preserved for up to 1300 years because of the low rate of wood decomposition in the severe cold. The wood remnants provide material to extend a ring-width chronology back to AD 645, and to date the lifespan of a large quantity of dead trees.

In order to estimate the downward displacement of the altitudinal treeline (the highest altitudinal position of open forest over the last millennium), a transect 430 m long and 20 m wide was set up on the southeastern slope of Rai-lz Massif, from the highest location of larch wood remnants (340 m above sea level) down to the present upper treeline (280 m). The transect was divided into 10 x 10 m quadrats. All of the wood remnants were

mapped and wood sections cut from the base of the trunk and roots were collected from each individual tree. The calendar year of establishment and death for each tree was determined by cross dating. Altogether, the life history of 270 dead trees was defined. In addition, 16 young living trees and seedlings were also mapped and their age determined.

Using these data, stages in the overall downward displacement of the upper treeline over the last 1150 years were reconstructed (Table 14.8). This time interval were divided into 5 periods, distinguished by differing directions of treeline shifts (rise or retreat in elevation) and differing rates of displacement. During the earliest period (430 years, AD 850–1280), the upper treeline rose from 305 to 340 m above sea level, an average of 1 to 2 m per decade. The highest altitudinal position reached by the treeline and the densest and most productive larch stands of the last millennium occurred in the 13th century. The second period (300 years, AD 1280–1580) was characterized by a substantial retreat of the upper treeline (from 340 m down to 295 m) at a mean rate of 2 to 3 m per decade. During the third period (210 years, AD 1580–1790), the treeline retreat stopped. The calculated rise (from 295 to 305 m, 0.5–1.0 m/decade) was not significant. The most extreme retreat was seen in the fourth period (120 years, AD 1790–1910), during which the upper treeline receded from 305 to down to 270 m, an average of 2 to 4 m per decade. During this fourth period, the upper treeline was at its lowest altitudinal position of the millennium. In the last period, from 1910 to the present, vigorous forest establishment took place on sites that were forested during the Middle Ages. The rate of change was the highest of the millennium (from 270 to 308 m, 4–6 m/decade).

The last period of expansion of forest vegetation is being studied using both direct and indirect evidence (old terrestrial, aerial, and satellite photographs; repeated stand descriptions of permanent plots and transects; morphology and age structure of stands; large-scale mapping within the ecotone; and meteorological and dendroclimatic data). Table 14.9 shows the change in area of different types of forest–tundra ecosystems within the ecotone during the 20th century. These data were obtained at the time of large-scale (1:10000) mapping of the key study area (3085 ha) located at the bot-

Table 14.9. Area change in different types of forest–tundra ecosystems from 1910 to 2000 in the Polar Ural Mountains (Shiyatov, 2003).

	Tundra with individual trees		Sparse growth of trees		Open forest		Closed forest	
	Area (ha)	Change (ha/decade)	Area (ha)	Change (ha/decade)	Area (ha)	Change (ha/decade)	Area (ha)	Change (ha/decade)
1910	2403		349		328		5	
		-76		37		24		15
1960	2021		535		450		79	
		-26		-52		36		42
2000	1917		327		593		258	

tom of Tchernaya Mountain. Three maps were produced that show the spatial distribution of these types of forest–tundra ecosystems in the beginning, middle, and end of the 20th century. Change in area was estimated for two periods: the 50 years from 1910 to 1960, and the 40 years from 1960 to 2000.

Between 1910 and 2000, the area of tundra with only scattered individual trees decreased significantly from 2403 to 1917 ha, or from 78 to 62% of the main study area. The greatest rate of change (-76 ha/decade) was observed during the first 50 years, when isolated seedling establishment above the treeline was the most intensive. Data obtained on the change in area of the sparse trees mapping unit is very interesting since during the first period the change was positive (+37 ha/decade) but during the second period it was negative (-52 ha/decade). The decrease occurred when young established trees began producing seeds, resulting in an increase in stand density (many stands changed from tundra with isolated trees into open forest). This led to the great increase in open-forest area between 1960 and 2000 (from 450 to 593 ha, +36 ha/decade). However, the most impressive changes were seen in the case of closed forests. The area of closed forest increased from 5 to 258 ha over the 90 years with the transformation of open forests into closed forests. To date, more than 550 repeated terrestrial photographs have been taken which can be used to reconstruct stand parameters for the middle of the 20th century.

Temperature increases during the 20th century were the major cause of the expansion of trees in the treeline ecotone. The mean June temperature at the Salekhard weather station (50 km east of the study area) increased from 7.2 ºC (1883–1919) to 8.5 ºC (1920–1998). The July mean increased from 13.8 to 14.3 ºC. Mean temperatures in the winter months (November–March) increased from -20.8 to -19.6 ºC. The average June–July temperature, which is critical for tree growth, increased from 10.5 to 11.4 ºC (0.9 ºC). This means that the June–July isotherm rose 120 to 130 m in altitude (in this area the elevational temperature gradient is 0.7 ºC/100 m). However, the mean rise of the upper treeline was only 20 to 40 m owing to a deficiency of viable seeds on sites remote from fertile trees and stands.

In this area, larch cones open and seeds are disseminated only on days with elevated temperatures, typically from the end of June to the end of July (Shiyatov, 1966). Wind is the primary method of seed dissemination; other means of dispersal, such as animals and birds, are insignificant. Since seed dissemination takes place in summer when snow cover is absent, it is difficult for seeds to be transported upwards over long distances. Heavy larch seeds are carried no more then 40 to 60 m from the tree and most of these seeds become lodged in lichen–moss and shrub layers that prevent them from germinating successfully. That is why abundant seedling establishment took place only close to individual trees and within existing stands.

Impressive changes have occurred in the structure of existing stands during the last 90 years. Most sites with trees have become much denser and more productive (up to 4 to 5 times) and many tundra sites located within the treeline ecotone have been afforested. The degree of afforestation increased from 22 to 38% (based on data from Table 14.9). Thus, many factors affecting the forest–tundra ecotone position reacted to summer temperature changes. However, for the purpose of climatic reconstruction, the best proxies for reconstructing summer temperature are those obtained from existing stands (tree rings, biomass, stand and canopy density, degree of afforestation) rather than treeline movement, which experiences lag effects. Although the displacement rate of the upper treeline is a good reflection of long-term climatic fluctuations (Table 14.8), reconstruction of actual temperature changes is complicated because of the response lag caused by the slow growth of seedlings and the lack of seeds on remote sites. For example, the recent warming observed in summer months is of the same degree as inferred for the Middle Ages (about 1 ºC) but the upper treeline has not yet reached the altitudinal position where forests grew in the 13th century. To overcome such discrepancies, it is necessary to use corrective factors. These will be different for each period and study area. For example, in the Polar Ural Mountains over the 90 years of study, the upper treeline rose 20 to 40 m in altitude but the June–July temperature isotherm rose 120 to 130 m. Therefore, reconstructed temperatures based on recent treeline movement should be increased by a factor of four.

Recent treeline movement in the Polar Ural Mountains can be confirmed as a widespread phenomenon by comparison of high-resolution satellite images. The satellite and *in situ* data analysis shows an increasing proportion of the area with higher stand crown closure. Specifically, in 1968 about 23.5% of the area supported stands with crown closure ≥30%; in 1998 this area had increased to 50.0%. The border of stands with closure ≤10% moved between 100 and 400 m horizontally, depending on the site. Some areas that were tree-covered before the LIA still do not support any trees.

14.11.1.4. Northeast Canada

Treeline does not always fluctuate in a straightforward way in response to the control of direct climate warming and cooling on the establishment and death of trees from seed, as illustrated in northeastern Canada. Treeline populations in northern Quebec are primarily single-species stands of black spruce, surviving in the upright growth form in protected sites, or in a damaged, low growth form where spruce are exposed to wind and snow abrasion above the snowpack. Spruce macrofossils are generally absent in the northern Quebec tundra zone, and the forest limit and soil charcoal limit occur together, strongly suggesting that the forest limit has remained stable during the last 2000 to 3000 years. Apparently, climate change does not easily trigger treeline advance or retreat in this location (Lavoie and Payette, 1996).

However, the character of the forest near the treeline has changed over the last few millennia. The Hustich (1966) hypothesis suggests that the regenerative capacity of forests decreases from south to north. At the treeline of northeastern Canada, summer climate is too cold for frequent seed production, although black spruce produce cones that fail to complete only the last stages of development (Sirois, 1999). The black spruce present today were established thousands of years ago in northern Quebec and have persisted by layering since then. Sporadic and patchy fires kill black spruce in this environment and, in the absence of seed production from nearby survivors, trees are eliminated in the local fire patches. By this process, the treeline of today, which is out of equilibrium with the environment that created it, has developed a more irregular and patchy boundary with time (Payette and Gagnon, 1985).

Since the 1960s and 1970s, small-tree stands have emerged above the snowpack, triggered by less harsh conditions associated with snowier winters in the last few decades (Pereg and Payette, 1998). This process decreases the numbers of low, damaged growth-form individuals in the population, and increases the numbers of upright, tree-form stems. The temperature increases projected by the ACIA-designated models are likely to be sufficient to provide the final requirement of summer warmth that would result in viable seed production at treeline in northeastern Canada (see Fig. 14.8 for summer temperature scenarios at Goose Bay, Labrador). The initial effect of warming is very likely to induce viable seed production within the forest–tundra zone, resulting in infilling of the patchy forest–tundra border. It is possible that production of viable seeds at the absolute tree limit would begin seed rain onto the tundra, a process that probably has not occurred in appreciable amounts for thousands of years.

14.11.2. Scenarios of future treeline movement

White et al. (2000) developed a global vegetation model to project how increasing atmospheric CO_2 concentrations and other parameters, such as air temperature and nitrogen deposition, affect vegetation composition and distribution and carbon sequestration in biomass and soils north of 50º N. The model, Hybrid v4.1, is a non-equilibrium, dynamic global vegetation model, with a sub-daily time step, driven by increasing CO_2 and transient climate output from the Hadley Centre GCM (HadCM2) with simulated daily and interannual variability. Three emissions scenarios (IPCC, 1995) were used: IS92a, which results in an atmospheric CO_2 concentration of 790 ppm by 2100; CO_2 stabilization at 750 ppm by 2225; and CO_2 stabilization at 550 ppm by 2150. Land use and future nitrogen deposition were not included. The model projects an expansion of the area of coniferous boreal forest and mixed/temperate forests of the Northern Hemisphere by about 50%. This forest expansion mainly displaces tundra, driven by the direct effects of rising CO_2 levels and temperatures on tree photosynthesis and growth. The forest expansion and an

associated increased carbon sink also depend on the indirect effects of increased nitrogen deposition and improved water-use efficiency. However, the model operates with only positive growth responses to increased temperatures, and new findings, such as negative growth responses in treeline trees to increased temperatures (section 14.7.3.1) and human activities forcing the treeline southward (Vlassova, 2002), suggest that the modeled increase in carbon uptake driven by forest expansion is unlikely to be fully realized.

The central Canadian Arctic is a region of low topographic relief and few barriers to tree migration, and is often depicted as an area of major northward tree movement in a straightforward response to increasing temperatures (e.g., Nuttall and Callaghan, 2000). The BIOME 1.1 model of potential natural vegetation under doubled atmospheric CO_2 conditions projects that about 60% of global tundra will be displaced, largely through the expansion of boreal forest (Skree et al., 2002). When the BIOME 1.1 model is forced with tripled CO_2 concentrations (see section 4.4.1, Fig. 4.12b), it projects that boreal forest will replace 70% of the tundra of northern Europe and virtually all the European Arctic coast will be occupied by what is today recognized as southern taiga or boreal forest (Cramer, 1997). These vegetation models of boreal forest response to climate change generally produce outputs based on the final adjustment of trees to occupy all climatically suitable areas. However, a variety of processes can reduce the potential for tree expansion or create environments that preclude tree establishment or survival, such as paludification (Skree et al., 2002). There is increasing evidence in the Russian Arctic of southward displacement of trees that are subject to strong maritime climate influences or intensified human land uses such as reindeer production systems (Vlassova, 2002). At the large scale, future northward movement of the treeline in response to climate change of the magnitude projected by the ACIA-designated models is very likely. However, a considerable lag period is possible, for example because of challenges to tree establishment (e.g., poor seedbed conditions in tundra) that must be overcome by repeated occurrences of low-probability events. Finally, environmental complexity and novelty in an altered, warmer world is likely to produce unexpected vegetation patterns at a local or regional scale.

14.12. Effects of ultraviolet-B on forest vegetation

During summer in the Arctic, levels of UV-B radiation are generally not much different than at mid-latitudes. However, the Arctic and Antarctic are uniquely susceptible to short-term, intense stratospheric ozone depletion, especially in their respective spring seasons. For general background on ozone depletion and UV-B radiation in the Arctic, see Chapter 5.

Exposure to increased UV-B (280–315 nm) radiation is known to inhibit plant growth, development, and

physiological processes. Long-lived, slow-growing plants such as trees may show cumulative effects of increasing UV-B radiation levels (Sullivan and Teramura, 1992). Effects of elevated UV-B radiation levels on plant processes vary in severity and direction and among species, varieties, and clones, as well as among plant parts and developmental stages. To avoid UV-B radiation, plants have developed screening mechanisms including increased leaf thickness or cuticle (Johanson et al., 1995; Newsham et al., 1996), optical structures to scatter and reflect UV-B radiation (Kinnunen at al., 2001), and the accumulation of UV-B screening phenolics and flavonoids in the epidermal cells of the leaves (Alenius et al., 1995; Cen and Bornman, 1993; Day, 1993).

Until the 1980s, relatively few plant species had been screened to determine the effect of enhanced levels of UV-B radiation. Some species show sensitivity to present levels of UV-B radiation while others are apparently unaffected by very large enhancements in UV radiation levels. Dicotyledonous crop plants such as peas (Day and Vogelmann, 1995) and canola seem to be more susceptible to increased UV radiation levels than cereals such as wheat (Beyschlag et al., 1989) and barley, although many other factors play an important role in sensitivity. Even varieties of the same species can exhibit substantial variability in UV-B radiation sensitivity (Teramura and Sullivan, 1994). About two-thirds of the few hundred species and cultivars tested appear to be susceptible to damage from increased UV-B radiation levels. Crop damage caused by UV-B radiation under laboratory conditions generally has been attributed to impairment of the photosynthetic process (Day and Vogelmann, 1995). In addition to gross disruption of photosynthesis, UV-B radiation may inhibit plant cell division as a physiological change, causing reduced growth and yields (Teramura and Sullivan, 1994). Accurately determining the magnitude of the effect of elevated UV-B radiation levels in the field is difficult, because interactions with other environmental factors, such as temperature and water supply, affect the reaction and overall growth of the crop (Balakumar et al., 1993, Mepsted et al., 1996).

Sensitivity to UV-B radiation differs among forest species and populations and is influenced by environmental conditions (Laakso and Huttunen, 1998; Lavola, 1998). The composition of flavonoids varies according to altitude and latitude. High-latitude, low-altitude species and populations are more sensitive (fewer protective mechanisms) to enhanced levels of UV-B radiation than low-latitude, high-altitude species and populations (more developed defense mechanisms), reflecting natural levels of exposure to UV-B radiation (Sullivan and Teramura, 1992). Scots pine populations growing at high latitudes are rich in prodelphinidin (Laracine-Pittet and Lebreton, 1988) and significant differences in the characteristics of UV-absorbing compounds occur among species of pine (Kaundun et al., 1998) and birch (Lavola, 1998).

Ultraviolet-B radiation has many direct and indirect effects on plant growth and development (Caldwell M. et al., 1998). The direct effects are most damaging because the photons of UV-B radiation cause lesions in important UV-B absorbing biomolecules such as nucleic acids and proteins (Caldwell C., 1993; Greenberg et al., 1989; Taylor et al., 1997). Photo-products of DNA formed by UV-B radiation are all toxic and mutagenic (Taylor et al., 1997) and altered DNA or RNA structures may interfere with transcription and replication causing slower protein synthesis as a result of UV-B radiation stress (Jordan et al., 1994; Taylor et al., 1997). The indirect effects of UV-B radiation on plants can also cause damage by the formation of free radicals and peroxides (Takahama and Oniki, 1997; Yamasaki et al., 1997). Excessive UV-B radiation levels can also alter patterns of gene activity (Caldwell M. et al., 1998).

Field studies in both crop plants and trees suggest that the primary effects of increased UV-B irradiance are subtle, light-induced morphological responses that alter carbon allocation (Bassman et al., 2003; Day, 2001). Recent UV radiation acclimation studies of subarctic and arctic plants have emphasized a multitude of responses ranging from avoidance and protective mechanisms to inhibition and accumulation of effects (Gwynn-Jones et al., 1999; Kinnunen et al., 2001; Laakso, 1999; Latola et al., 2001; Turunen et al., 2002). Enhanced UV-B radiation levels affect litter decomposition directly (photodegradation and mineral nutrient cycling) and indirectly (chemical changes in plant tissues) and also affect the biochemical cycling of carbon (Rozema et al., 1997). Both direct and indirect effects include physical, chemical, and biological components. The indirect effects of UV-B radiation are likely to be more significant than direct effects in subarctic and arctic forest ecosystems.

Subarctic conifers are long-lived with long generation times; damage from UV-B radiation is likely to accumulate over the years. Winter injuries to evergreens are caused by the interaction between freezing, desiccation, and photo-oxidation (Sutinen et al., 2001). In subarctic and arctic conditions, late-winter cold temperatures, enhanced UV radiation levels from intense solar radiation, and water deficiency are the major environmental risks. Xeromorphic leaves and small leaf size of subarctic and arctic trees reduce evapo-transpiration. However, late spring in high-latitude subarctic and arctic ecosystems is characterized by high levels of solar radiation and fluctuations between freezing and thawing temperatures. The UV radiation dose received by evergreens in the late winter, early spring, and at the beginning of the short growing season is high due to reflectance from persistent snow cover. Some earlier studies considered evergreens to be tolerant, but other studies have revealed evergreens to be sensitive to enhanced UV-B radiation levels (Kinnunen et al., 2001; Laakso et al., 2000; McLeod and Newsham, 1997).

Experimental field evidence indicates that enhanced UV-B radiation levels mainly increase the amount of soluble UV-B-absorbing compounds in summergreen (deciduous) plants (Searles et al., 2001), but the protective functions of wall-bound phenolic compounds and epicuticular waxes in evergreens are more complicated. The responses are species-specific among pine species (Laakso et al., 2000).

In needles from mature subarctic Scots pine, enhanced UV-B radiation levels induced xeromorphic (change in plant anatomy to enhance drought resistance) characteristics, including smaller epidermal area and enhanced development of the cuticle layer (Latola et al., 2001). Ultraviolet responses increased the concentration of UV-B radiation absorbing compounds in the epidermal cells and induced high and accumulating proportions of oxidized glutathione (Kinnunen et al., 2001; Laakso et al., 2001; Latola et al., 2001; Turunen et al., 1998, 1999). The cumulative stress has been measured as gradually decreased total glutathione and an increased proportion of oxidized glutathione levels in one- to three-year-old needles (Laakso et al., 2001; Laakso and Huttunen, 1998).

The most consistent field response to enhanced UV-B radiation levels (Day, 2001; Searles et al., 2001) is an increase in concentrations of soluble or wall-bound UV-B radiation absorbing compounds in leaves, complicated by great seasonal, daily, and developmental variation, both in epicuticular and internal compounds. It is important to remember that not all soluble flavonoids are UV-inducible (Lavola, 1998) or acid-methanol extracted (e.g., cell-wall bound UV-B absorbing phenylpropanoids; Jungblut et al., 1995).

Increased amounts of epicuticular waxes and UV-absorbing compounds, such as flavonoids, and smaller leaf/needle surface area are plant defense mechanisms against UV-B radiation. In young Scots pine seedlings, UV-B radiation induces flavonoid biosynthesis (Schnitzler et al., 1997). However, an increase in UV-B absorbing compounds may result in a decrease in cell expansion and cell-wall growth (Day, 2001). Diacylated flavonol glucosides provide protection from UV-B radiation (Turunen et al., 1999) and biosynthesis of these compounds and the development of waxy cuticles appears to provide effective UV radiation protection in young needles (Kinnunen et al., 2001; Laakso et al., 2000). The protective effects come about through rapid development of epicuticular waxes, an increase in cutinization, and an initial increase followed by inhibition of UV-screening compounds (Kinnunen et al., 2001; Laakso et al., 2000).

Plant-surface wax morphology, chemistry, and quantity respond to environmental changes. Many diols (Turunen et al., 1997) are important as reflectors to avoid harmful UV radiation, but they also absorb in the UV spectrum. In many tree species, phenolics and other UV-protective substances are situated in the cuticle. The role of epicuticular waxes has been considered mainly to provide reflectance of UV radiation, but some wax components, for example, secondary alcohols (e.g., nonacosan-10-ol) and β-diketones, absorb UV radiation (Hamilton, 1995). Naturally established treeline Scots pines in a study site at Pallas-Ounastunturi National Park, Finland, were exposed to enhanced UV-B radiation levels during the full period of arctic summer daytime. The average needle dry weight increased and the wax content decreased in the UV-treated trees. The responses were observed both in the previous and current needle year (Huttunen and Manninen, in press).

A long-term study of silver birch conducted over three growing seasons showed changes in growth (i.e., shorter and thinner stems), biomass allocation, and chemical protection, while the effects on secondary metabolites in the bark were minor (Tegelberg and Julkunen-Tiitto, 2002). The changes did not occur until the third growing season, demonstrating the importance of long-term studies and the cumulative effects of UV-B radiation. A three-year study of Scots pine showed how varying defense mechanisms within the season, needle age, and developmental stage protected the Scots pine needles against increased UV-B radiation levels (Kinnunen et al., 2001). However, protective pigment decreased during the third year of exposure, suggesting that cumulative UV-B radiation exposure affects defense mechanisms and possibly makes these defenses insufficient for long-term exposure.

Quantitative changes were detected in secondary metabolites (plant chemicals) in leaves of dark-leaved willow (*Salix myrsinifolia*) exposed to enhanced UV-B radiation levels (Tegelberg and Julkunen-Tiitto, 2001). The changes in amount of secondary compounds are likely to have indirect effects at the ecosystem level on willow-eating insects and their predators, and on the decomposition process. Both dark-leaved and tea-leaved willow (*S. phylicifolia*) showed chemical adaptations to increasing UV radiation levels. However, the chemical adaptations were based more on clone-specific than on species-specific responses (Tegelberg and Julkunen-Tiitto, 2002). Several types of phenolic compounds in seedlings of nutrient-limited silver birch respond to UV-B irradiance, and seedlings are less susceptible to UV radiation when grown in nutrient-limiting conditions (Lavola et al., 1997). However, changes in secondary metabolites of birch exposed to increased UV-B radiation levels might increase its herbivore resistance (Lavola et al., 1997). A lower level of animal browsing on birch because of this chemical change induced by increased UV-B radiation levels could possibly improve the performance of birch over its woody plant competitors. Silver birch exposed to UV-B radiation with nutrient addition also displays an efficient defense mechanism through production of secondary metabolites, and demonstrates the additive effects of nutrient addition (de la Rosa et al., 2001). These results clearly establish that UV-B radiation plays an important role in the formation of secondary chemical characteristics in birch trees at higher latitudes (Lavola, 1998).

14.13. Critical research needs

14.13.1. Agriculture

This chapter focused mainly on annual crops and used GDD changes to estimate the likely effects of climate change on northern agricultural potential. Future assessments should include in-depth analyses of perennial crops and livestock, including scenarios of non-climate factors such as markets and public-sector policies. Better climate/crop models specific to agriculture in high-latitude regions (i.e., special crop varieties, long day-length effects) are also needed for future assessments. The effects of temperature increases and moisture changes on soil processes should be an integral part of the modeling systems. Future assessments should include many more climate stations in the boreal and arctic regions. The insect, disease, and weed issues that might accompany climate change and expanded agriculture should be addressed, particularly those with a unique high-latitude dimension unlikely to be part of ongoing studies in more southerly locations.

Given the critical role of public policy in agriculture in the region, an important issue is to identify national and international policies that might accommodate expansion of specific crops in the Arctic and subarctic. The infrastructure change needed to accommodate climate change should be identified along with the economic impacts of constructing new infrastructure and the economic impacts once such projects are constructed.

14.13.2. Boreal forests and climate change

Given the large contribution of the boreal forest to the terrestrial carbon sink, and the large stocks of carbon stored in it, the health and vigor of the forests of this region are a particularly significant input to climate change policy, science, and management. Climatic models, recorded data, and proxies all indicate that there are significant spatial differences in temperature anomalies and associated tree growth changes around the globe. Not all species and relatively few forest site types have been examined to determine the strength and components of climate controls on tree growth. In order to determine the current and probable future carbon uptake of the boreal forest, these spatial differences in climate change and tree growth need to be systematically identified, both in the contemporary environment and in the recent historical past. Particular attention should be given to ways of effectively combining ground-level studies, which clarify mechanisms of control and provide a historical perspective, with remote-sensing approaches, which provide comprehensive spatial coverage that can be easily repeated and updated.

Trees and forest types that change their level of sensitivity to climate or even switch their growth responses to temperature are of particular interest. If climate controlled growth more at some times and less at other times in the past, tree-ring data used to reconstruct past climates will contain biases from the recorded climate data they are calibrated to, especially if the calibrating climate data cover a short time period. It is important to establish whether this change or reduction in tree growth–climate relationships is unique to the 20th century, whether the climate change of recent decades is largely responsible for growth declines, and finally, whether the mechanism of climate control is direct or indirect.

In order to better understand, measure, and project the rapid transformations that are possible in the boreal forest, better information is needed about the role of climate and forest condition in triggering major fire and insect disturbances. The specific characteristics of fires that result in maximum production of charcoal, which represents an important form of long-term carbon sequestration, are not well documented. Further insight is needed into the interaction of climate, forest disturbance, forest succession (and its influences on carbon dynamics), water and nitrogen dynamics, and changes in carbon stocks.

Forest advance into tundra has the potential to generate a large positive temperature feedback. Unfortunately, the understanding of change at this crucial ecological boundary comes from a small number of widely separated studies undertaken to achieve many different objectives. A coordinated, circumpolar treeline study and monitoring initiative will be necessary to address definitively the question of how and why this boundary is changing at the scale required to address its potential global importance.

Improvements in scaling output from GCM grid data to applications at a given location will improve confidence in scenario projections.

14.13.3. Boreal forests and ultraviolet-B radiation

The UV-radiation survival strategies of evergreens appear to include simultaneous inhibition and avoidance. Late-winter and early-spring conditions are critical, and their importance should be studied further and effects quantified. More studies, longer-term studies, and well-designed ecosystem studies that incorporate the previously established effects from individual plot studies and consider the multiple influences of UV-B radiation on plant chemistry in settings of ecological communities will be needed to understand the cumulative effect of increased UV-B radiation levels on forests at high latitudes.

Summary

The nature of projected climate-related changes and variability, and the characteristics of arctic populations, means that impacts of climate change on the health of arctic residents will vary considerably depending on such factors as age, gender, socio-economic status, lifestyle, culture, location, and the capacity of local health infrastructure and systems to adapt. It is more likely that populations living in close association with the land, in remote communities, and those that already face a variety of health-related challenges will be most vulnerable to future climate changes. Health status in many arctic regions has changed significantly over the past decades and the climate, weather, and environment have played, and will continue to play a significant role in the health of residents in these regions.

Direct health impacts may result from changes in the incidence of extreme events (avalanches, storms, floods, rockslides) which have the potential to increase the numbers of deaths and injuries each year. Direct impacts of winter warming in some regions may include a reduction in cold-induced injuries such as frostbite and hypothermia and a reduction in cold stress. As death rates are higher in winter than summer, milder winters in some regions could reduce the number of deaths. Direct negative impacts of warming could include increased heat stress in summer and accidents associated with unpredictable ice and weather conditions. Indirect impacts may include increased mental and social stress related to changes in the environment and lifestyle, potential changes in bacterial and viral proliferation, vector-borne disease outbreaks, and changes in access to good quality drinking water sources. Also, some regions may experience a change in the rates of illnesses resulting from impacts on sanitation infrastructure. Impacts on food security through changes in animal distribution and accessibility have the potential for significant impacts on health as shifts from a traditional diet to a more "western" diet are known to be associated with increased risk of cancers, diabetes, and cardiovascular disease.

Increased exposure to ultraviolet (UV) radiation among arctic residents has the potential to affect the response of the immune system to disease, and to influence the development of skin cancer and non-Hodgkin's lymphoma, as well as the development of cataracts. However, as the current incidence rates for many of these ailments are low in small arctic communities it is difficult to detect, let alone predict, any trends in their future incidence. The presence of environmental contaminants threatens the safety of traditional food systems, which are often the central fabric of communities. The projected warming scenarios will affect the transport, distribution, and behavior of environmental contaminants and thus human exposure to these substances in northern regions.

These changes are all taking place within the context of cultural and socio-economic change and evolution. They therefore represent another of many sources of stress on societies and cultures as they affect the relationship between people and their environment, which is a defining element of many northern cultures. Through potential increases in factors influencing acculturative stress and mental health, climate-related changes may further stress communities and individual psychosocial health. Communities must be prepared to identify, document, and monitor changes in their area in order to adapt to shifts in their local environment. The basis of this understanding is the ability to collect, organize, and understand information indicative of the changes taking place and their potential impacts. A series of community indicators are proposed to support this development of monitoring and decision-making ability within northern regions and communities.

15.1. Introduction

15.1.1. Background and rationale

The arctic regions share common characteristics such as sparse population, harsh climate, similar geographic features, high latitude, and characteristic seasonal extremes of daylight hours and temperatures. The modern climate record shows that regions of the same high latitude often have very different mean annual temperatures, precipitation regimes, and ecosystems. It is important to incorporate this diversity in any assessment of the current and future impacts of climate change on the health of northern peoples.

In general, arctic regions of the United States, Canada, and Nordic Europe have more economic support than those of the former Soviet Union. As a result, the availability and quality of data on human health status vary widely and are not available for some regions. The evaluation, both current and future, of the impact of climate change on human health is entirely data dependent.

As a result, this chapter (unlike those addressing specific climate issues) cannot address the potential health impact of climate change using a regional or time-specific approach.

The ACIA-designated models project climate change relative to baseline conditions (1981–2000) for three 20-year "time slices" (2011–2030, 2041–2060, and 2071–2090) for four arctic regions. The time-slice regional scenario is a useful construct for those ecological components which are not able to quickly relocate or utilize technology to mitigate climate-related impacts, but is not as useful for human populations, where non-climate factors can cause mass relocations over periods of days to weeks. The reactor accident at Chernobyl in 1986 is one such example. Also, economic decisions such as those to develop natural resources (e.g., petroleum, minerals, timber) can bring food, education, and health resources to a region, and may accelerate or mitigate a decrease in numbers of a traditional food species. These changes might result in population growth and an improvement in health status,

or the erosion of a community's cultural base, bringing cultural stress and a deterioration in health status.

This chapter does not attempt to predict health impacts for any specific region, or any specific time frame, for the following reasons.

- Climate models, over prolonged intervals (decades), are uncertain, and thus impacts on people and their communities are also uncertain.
- Humans can adopt strategies to mitigate almost any possible health impact, given sufficient support.
- Levels of governmental, public health, social, and cultural support vary dramatically among circumpolar communities and will continue to fluctuate in the future.
- Over the past four decades, many regions of the circumpolar arctic have shown a warming trend, however significant areas have also shown a cooling trend, such that uniform temperature assumptions can not yet be justified.

This chapter presents a discussion of mechanisms by which climate can influence human health in arctic communities such that these communities might plan appropriate monitoring strategies to support the development of adaptive or mitigation actions. In this way, potential negative impacts might be recognized and mitigated, and potential opportunities might be recognized and exploited.

15.1.2. Health in the circumpolar Arctic

According to the World Health Organization (WHO, 1967), health includes aspects of physical, mental, and social well-being and is not simply the absence of disease. In this holistic vision of health, which is very similar to that supported by the many indigenous groups throughout the world, the well-being of individuals and communities is tied to that of their environment. Human health status is a result of the complex interaction of genetic, nutritional, and environmental factors. "Environment" in this context includes the socio-economic, cultural, and physical infrastructure and ecosystem factors. Many of these groups of factors can improve or degrade health status, by enhancing the resilience of a population, or by causing stress. In these instances, the stress can be a direct physical change such as temperature, can take the form of increased prevalence of a disease-causing organism, or be represented by a perceived threat or sense of loss, engendering psychological stress.

Previous reports have concluded that, for the residents of the contiguous United States, climate change will have a small overall health impact, due to the ability of the existing public health system to respond to new threats (Patz et al., 2000). This conclusion is unlikely to be true for the North American Arctic, or for arctic residents in many other countries, for the following reasons.

- Many arctic residents live in very small, isolated communities, with a fragile system of economic support, dependence on subsistence hunting and fishing, and little or no economic infrastructure.
- Rural arctic public health and acute care systems are often marginal, sometimes poorly supported, and in some cases, non-existent.
- Culture is often critical to community and individual health, and may be affected by climate change via mechanisms such as the loss of a traditional subsistence food source, which can result in a grief response and severe stress. Climate changes can become a source of illness, injury, and mortality for arctic communities.

The combined result of these factors is that rural arctic residents are often uniquely vulnerable to health impacts from climate change, mediated by a variety of mechanisms. Also, owing to their close relationship and dependence on the land, sea, and natural resources for cultural, traditional, social, economic, and physical well-being, indigenous peoples are also uniquely vulnerable to these environmental changes. It is for these reasons that this chapter emphasizes potential climate impacts on health in small arctic communities, among whose residents many are indigenous.

This chapter presents a brief overview of available data on the current health status of arctic residents, followed by a series of sections describing the potential impact mechanisms of climate change on socio-cultural and socio-economic environments and physical infrastructures as they relate to human health. Sets of indicators are then proposed to prospectively monitor potential climate change impacts on human health. The chapter concludes with recommendations for research and action.

15.2. Socio-cultural conditions, health status, and demography

Social conditions and lifestyles among indigenous populations vary widely throughout the Arctic. Many indigenous peoples rely on the food that they hunt and harvest from the land and sea, as it provides for much of their nutritional intake as well as being a critical component of their cultural identity, and in many cases, their local informal economy (Duhaime, 2002). Members of the urban population, of whom many are of European descent, have lives that are to some extent indistinguishable from those of their kinfolk in Europe or North America, although the arctic climate still determines much of their daily life and is an underlying condition for infrastructure and transport.

15.2.1. Socio-cultural conditions and health status

Living conditions are changing throughout the Arctic for indigenous as well as non-indigenous residents as a consequence of the change from an economy based on hunting to modern wage earning (AMAP, 2003). The following description of social change in Greenland (Bjerregaard and Curtis, 2002) is similar to that in many other circum-

polar regions. The shift from a traditional Inuit community to a modern society started at the beginning of the 20th century when fishing began to replace the hunting of marine mammals as the main source of livelihood. This was accompanied by population movement from a large number of small villages to larger – although still small by many standards – population centers, and by the gradual supplement of the traditional subsistence economy by a cash economy. By the end of the Second World War, however, Greenland still had a relatively isolated and traditional society where most people lived in small villages and subsisted on small-scale hunting and fishing activities. During the latter half of the 20th century unprecedented changes occurred in Greenland resulting in a very modern society thoroughly integrated in global political and economic systems. Fishing and the associated processing industry are the basis of the present economy but at a very advanced level with ocean-going fishing vessels existing alongside smaller crafts and some fishing from the ice. Subsistence hunting and fishing are still widespread but are increasingly becoming a leisure activity. Daily connections by air to Denmark now exist, and even small villages have telephone service and internet access. Supermarkets contain products such as fresh mangos and papayas, as well as a range of European meats, dairy, and vegetable products, and frozen Greenlandic fish and seal meat.

The influence of such changes on physical health and everyday life are obvious; positive changes include vastly improved housing conditions, a stable supply of food and increased access to western goods, and decreased mortality and morbidity from infectious diseases including tuberculosis. However, societal change and modernization have also brought a number of social and mental health problems as well as increasing prevalence of chronic diseases such as cardiovascular diseases and dia-

betes (Bjerregaard and Young, 1998). Children have been brought up with values that were useful for hunters and hunters' wives living in small communities: independence, self-reliance, non-interference with other people's lives, and physical strength. As adolescents and adults they have had to cope with life in much larger and more densely populated communities, in a world that rewards formal education, language skills, and discussion instead of action. The majority of individuals have adjusted to the new situation but for some the burden has been a significant challenge. In some cases, these changes have been associated with historical changes in climatic conditions. The relationship between climate and settlement in Greenland illustrates the complexity of these changes in arctic communities (see Box 15.1).

Over the last 50 years, the population of most arctic regions has dramatically increased. Much of this increase is due to a reduction in infant mortality and mortality from infectious diseases, particularly tuberculosis and the vaccine preventable diseases of childhood. Also, safe water supplies, sewage disposal, development of rural hospitals, and in some regions, community-based medical providers, have contributed to improved care and access to care for injuries and illness. All regions have greatly improved transportation infrastructure, resulting in the availability of western food items, tobacco, and alcohol on a scale not previously possible. Plus, in many arctic regions communications technology has made western culture visible in even the most remote settlements. Arctic indigenous residents are, in most regions, encouraged to become permanent residents in fixed locations, to facilitate the provision of services and economic opportunities. This has eliminated the historic practice of families and groups of families to move, intact, when climate or other environmental change made a region

Box 15.1. Climate change impacts on settlement in Greenland

In the early 20th century, climate warming resulted in Atlantic cod (*Gadus morhua*) appearing in great shoals off the west coast of Greenland. Cod fishing became a source of cash income for the Greenlanders and the traditional society based on hunting of seals and whales began to make way for a modern fishing society and cash economy. The population of Greenland concentrated in fewer and larger towns and the number of villages decreased. This development was intensified after the Second World War due to deliberate concentration of the population in towns with schools, health care, and shops. Fishing was planned to be the major source of revenue for the Greenland society. In the 1960s, however, climate cooling together with overfishing resulted in the disappearance of cod from the west coast of Greenland (Hamilton et al., 2003) (see also section 15.5.5.3).

In the 1960s, large numbers of shrimp were detected in Disko Bay. Over the course of a few years, the village of Qasigiannguit with a population of only 343 in 1955 developed into a lively town centered on the shrimp factory. During the 1990s, the shrimp disappeared from the coastal waters. Large sea-going vessels now fish and process the shrimp far from the coast and the factory has closed. People have started moving from the town. In 1982 when the population was at its maximum there were 1800 inhabitants; in 2000 the population of Qasigiannguit was only 1400. The unemployment rate is among the highest in Greenland: 14.4% compared to 7.1% in the towns in general.

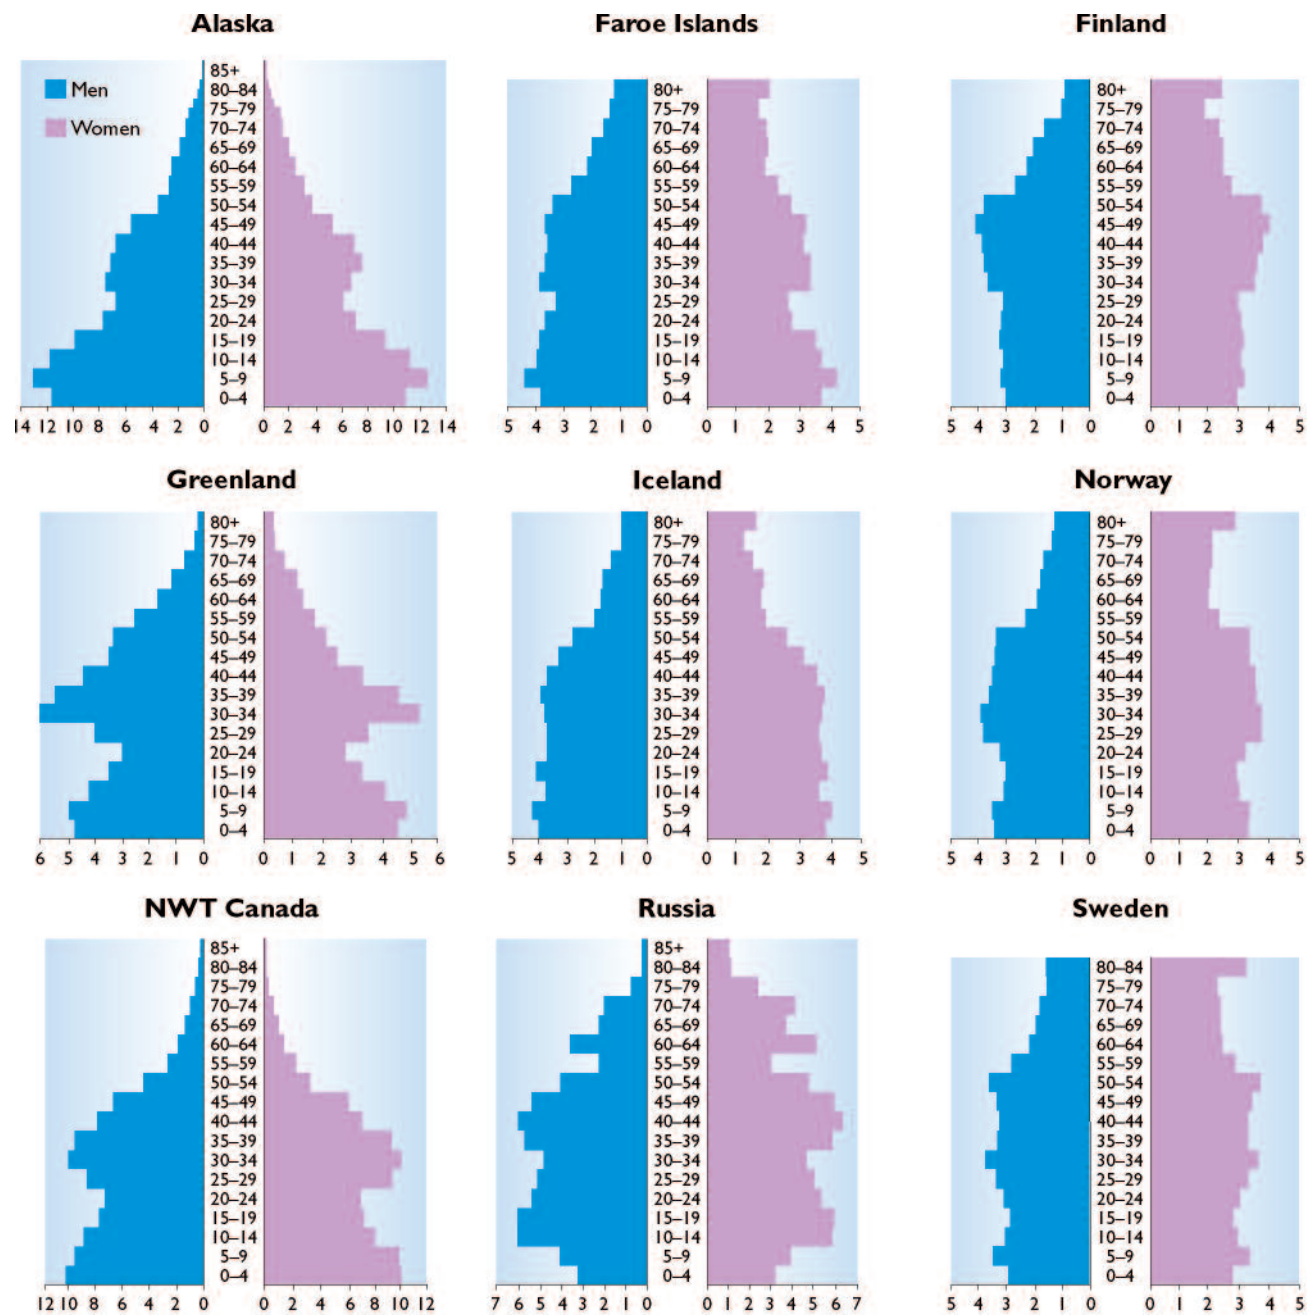
The examples show how climate change can influence the occurrence of commercially important species and how the disappearance of a species can have negative impacts on socio-economic conditions within a local community. Many Inuit communities are particularly vulnerable to changes in species availability because they often rely on the availability of only one or a few species.


Fig. 15.1. Age structure of arctic populations (WHO, 2000).

unable to sustain them. Also, there are often few products or services that many small communities can contribute to the overall economy, such that survival often depends on a complex web of government-funded economic support, combined with primarily service-based employment in schools, sanitation facilities, and transportation infrastructure. The establishment of fixed village locations has also affected subsistence activities.

Indigenous culture is under stress from competing western culture, and subsistence activities are affected by climate change and concerns about the contamination of traditional food resources by contaminants, both from local sources and from long-range sources transported to the Arctic via ocean and atmospheric currents. Zoonotic diseases (animal diseases that can be passed to humans) and parasitic diseases are also associated with some tradi-

tional food species and traditional food preparation methods (e.g., trichinosis or botulism). Assessments of food safety have resulted in the collection of information on micronutrients and anthropogenic chemicals and have often resulted in the release of confusing or conflicting messages to rural residents (AMAP, 2003; CACAR II, 2003). As a result, erosion of cultural support, a decrease in traditional activities, and substitution of western foods for traditional foods are becoming more important as the causes of morbidity and mortality among arctic populations such that, in some respects, they now more closely resemble western populations.

Historically, there was little heart disease, cancer, obesity, or diabetes in circumpolar populations. Major causes of mortality were infectious diseases, especially tuberculosis, pneumonia, and injury. Life expectancy was short,
Fig. 15.2. Life expectancy in arctic populations (IHS, 1999b; WHO, 2000).

and infant mortality was high (Bjerregaard and Young, 1998). However, for the reasons discussed in this section much has now changed. Section 15.2.2 presents the current population structure, birth rates, infant mortality, and causes of adult mortality for the countries with arctic residents. Arctic regions of the Russian Federation have few comparable data but there is no reason to believe that this region does not also have similar serious health problems as seen elsewhere.

Many technological advances have made subsistence hunting safer, such as modern protective clothing, Global Positioning System (GPS) devices, radio, cellular telephones, and weather forecasts. Hunting efficiency has also improved dramatically through the use of modern firearms and improved transportation, such as boats, snowmobiles, all terrain vehicles, and aircraft. These advances have the potential to erode traditional knowledge and skills, which could increase risk. For instance, loss of traditional knowledge of short-term weather changes and ice thickness could result in injury or death.

15.2.2. Population structure and health statistics

Some regions of the Arctic have a different population structure compared to that of more temperate regions of the same country. This is true for the indigenous rural arctic populations; including Alaska Natives, Canadian Arctic indigenous groups, Inuit, and Greenland Inuit.

The populations of the Northwest Territories (NWT, including Nunavut) and the Yukon (which are predominantly indigenous), as well as Alaska Natives and Greenland residents (who are 90% Inuit), have a greater percentage of children and a smaller percentage of older people than in the Nordic countries (Fig. 15.1; AMAP, 2002). These three groups represent the majority of rural arctic residents for whom comparable health data exists. All these groups typically reside in very small communities (of around 50 to 5000 inhabitants), in remote regions, and with traditional foods comprising a significant part of the diet.

The health of arctic populations can be determined from a range of health status indicators, including life
Fig. 15.3. Birth rates by age group in arctic populations (IHS, 1999b; WHO, 2000).

expectancy at birth, birth rate, infant mortality, population mortality, and age-adjusted causes of death.

15.2.2.1. Life expectancy

Life expectancy in arctic populations has improved owing to a wide variety of changes in social conditions and lifestyles. A significant contributor to improved life expectancy is decreased infant mortality. Alaska Natives, NWT residents, and Greenland residents generally have lower life expectancies than residents in the Nordic countries and on average, life expectancy is lower for indigenous populations (Fig. 15.2; Statistics Canada, 2003).

15.2.2.2. Birth rate

Alaska Natives, NWT residents, and Greenland residents have higher birth rates than residents in the Nordic countries (Fig. 15.3). This reflects the greater proportion of children in these populations.

15.2.2.3. Infant mortality

Infant mortality has decreased considerably since around 1950 for Alaska Natives (Fig. 15.4). Despite the improvement the overall infant mortality rates for indigenous arctic residents in Alaska and Greenland remain higher than for all races infant mortality rates in the United States and Canada. Infant mortality rates are lowest in the Nordic countries.

15.2.2.4. Common causes of death

Differences also exist in the most common causes of death based on death certificate data. To account for differences in population age structure (see Fig. 15.1) the mortality rates were adjusted to those for a standardized population structure; although the standard population structure used for the Nordic countries is slightly different to that for Canada and the United States. Figure 15.5 compares death
Fig. 15.4. Rates of infant mortality in Alaskan Natives and all races U.S. infants (IHS, 1999b; WHO, 2000).

Fig. 15.5. Common causes of death in arctic populations (IHS, 1999b; WHO, 2000).

rates for a range of conditions in indigenous populations (or largely indigenous in the case of the NWT) and the American and European populations. It is evident that Alaska Natives and Greenland residents have much higher mortality rates for injury and suicide. Mortality rates for heart disease and cancer are now similar in arctic indigenous populations and in relation to overall rates for the United States, Canada, and Northern European countries.

15.3. Potential impacts of direct mechanisms of climate change on human health

Human health in northern communities is affected via a number of direct and indirect impacts of climate-related changes. "Direct impacts" refers to those health consequences resulting from direct interactions with aspects of the environment that have changed or are changing with local climate (i.e., resulting from direct interactions with physical characteristics of the environment: air, water, ice, land; and for example exposure to thermal extremes). They include such things as difficulties in dealing with heat and cold stress; alleviation of cold stress due to warmer winters; dangers associated with travel and activities on the land resulting from unpredictable weather patterns and ice conditions; and increased incidences of sunburn and rashes as a result of increased sun intensity and exposure to UV-B radiation.

The direct impacts of climate and UV radiation on human health are primarily related to extreme events, temperature, and changes induced by exposure to UV-B radiation. Much of the discussion in this section on the mechanisms involved in these potential impacts involves associations of health events with observed climate change, without assigning causality. Where the effects are understood, the mechanisms are described. However, in many instances, the exact mechanisms are not known, or the relationships between human health and climate variables are multifaceted.

15.3.1. Extreme events

Some reports indicate that extreme weather events such as droughts, floods, and storms may become more frequent and intense in the future (Haines and McMichael,
1997) and there is some evidence that this is already occurring (see Krupnik and Jolly, 2002). Injury and death are the direct health impacts most often associated with natural disasters. Precipitation regimes are expected to affect the frequency and magnitude of natural processes which can potentially lead to death and injury, such as debris flow, avalanches, and rock falls (Koshida and Avis, 1998).

Thunderstorms and high humidity have been associated with short-term increases in hospital admissions for respiratory and cardiovascular diseases (Kovats et al., 2000). According to Mayer and Avis (1997), there is controversy concerning the incidence and continuation of significant mental health problems, such as post traumatic stress disorders following natural disasters. An increase in the number of mental health disorders has been observed in the United States after natural disasters. Longer periods of extreme weather and storm events could have social impacts on communities that are isolated from regional centers and if major modes of transport are no longer available. The impacts of extreme events on everyday subsistence activities could also affect community and individual well-being.

Indigenous people throughout the Arctic have reported that the weather has become more "unpredictable" and in some cases that extreme or storm events progress more quickly today than in the past (Fox S., 2002; Furgal et al., 2002; Krupnik and Jolly, 2002). Some northern residents report that this unpredictability limits subsistence activities and travel and increases the risks of people being trapped by weather while outside the community (Fox S., 2002; Furgal et al., 2002; Krupnik and Jolly, 2002; see Chapter 3).

> *Yeah, it changes so quick now you find. Much faster than it used to… Last winter when the teacher was caught out it was perfect in the morning, then it went down flat and they couldn't see a thing. It was like you were traveling and floating in the air, you couldn't see*

*the ground. Eighteen people were caught out then, and
they almost froze, it was bitterly cold.* Labrador hunter,
as quoted in Furgal et al., 2002

15.3.2. Temperature-related stress

Warming is projected for some regions of the Arctic
(see Chapter 4), and this may result in an increase in the
number and magnitude of extreme warm days. Exposure
to extreme and prolonged heat is associated with heat
cramps, heat exhaustion, and heatstroke. However,
because of the low mean temperature in many arctic
regions, the likelihood of such events having large impacts
on public health for the general population is low. Death
rates are higher in winter than in summer and milder
winters in some regions could actually reduce the num-
ber of deaths during winter months. However, the rela-
tionship between increased mortality and winter weather
is difficult to interpret and more complex than the associ-
ation between mortality and morbidity and exposure to
high temperatures (Haines and McMichael, 1997; Patz et
al., 2000). For example, many winter deaths are due to
respiratory infections such as influenza and it is unclear
how influenza transmission would be affected by warmer
winter temperatures. Some studies indicate an association
between extreme temperature-related events and mortal-
ity. For these associated impacts, groups such as the elder-
ly and people affected by cardio-respiratory problems are
more vulnerable (Patz et al., 2000).

In North America, summer heat waves affect more
urban populations than northern people, especially
because of the urban heat-island effect (Kovats et al.,
2000). The impact is greater when the high temperatures
(>25 ºC) are irregular and occur at the beginning of
summer (Thouez et al., 1998). Indigenous people in
some regions of the Arctic are reporting incidences of
stress related to temperature extremes not previously
experienced. For example, shortness of breath and
reduced physical activity (e.g., fishing), and an increase
in respiratory discomfort (Furgal et al., 2002).

Fewer cold days, associated with a general warming
trend in some regions during winter, are reported to
have the positive effect of allowing people to get out
more in winter and so alleviate stress related to extreme
cold (Furgal et al., 2002). However, in Nunavik for
example, approximately one to two heat waves occur
every 30 years while extreme cold is much more com-
mon. In regions where heat waves do not represent a
real risk for northern populations, an increase in
extreme cold events could have more serious implica-
tions. According to Dufour (1991), respiratory problems
were responsible for one in seven deaths among the Inuit
population of Nunavik. Muir (1991) reported that respi-
ratory problems were the primary reason for visits to the
nurse or doctor. Chronic respiratory illnesses are highly
prevalent in some northern regions. For example, in
Labrador, breathing problems are among the most com-
mon long-term medical conditions in adults and children
(LIA, 1997). In these two northern Canadian regions,

chronic respiratory illnesses could be amplified by pro-
longed cold events. Indirect effects of prolonged cold
events could also occur as other public health problems
are further aggravated. For example, spending a longer
period of time in crowded and overheated houses during
prolonged cold periods could affect the transmission of
viral infections, especially among the elderly, the young,
and the physiologically vulnerable (e.g., individuals who
are immunosuppressed due to the presence of other dis-
eases or medication). Other factors such as smoking can
also modify the incidence of respiratory illnesses.

In the 1970s, scientific research focused for the first
time on dramatic rises in mortality every winter, and
on smaller rises in unusually hot weather. Heat-related
deaths often result from severe dehydration (causing
hemoconcentration) resulting from the loss of electro-
lytes and water in sweat and the inability to regulate body
temperature. In northern Sweden, a clear association
between atmospheric pressure, changing temperature,
and increasing rates of cardiac events was documented
(Messner et al., 2003). Exposure to low ambient temper-
atures for long periods brings specific physiological
stresses. Cold exposure is part of daily working life in
the Arctic. It affects human outdoor activity significantly
because the arctic winter is long and cold conditions are
severe. Winter, with mean temperatures of less than
0 ºC, lasts for more than seven months in some regions.
The interactions between temperature (in this case cold)
and health, and the various health consequences are
summarized in Fig. 15.6. Responses to cold may be nor-
mal, exaggerated (hyperreactions), or damped (hypo-
reactions). These result in eventual body cooling and
associated impacts. In some instances, hyperreactions may
occur which themselves result in disease. Climate models
project that cool winter temperatures will persist in
many circumpolar regions (see Chapter 4). Cold is likely
to remain an environmental cause of illness and death.

15.3.2.1. Limits of human survival in the thermal environment

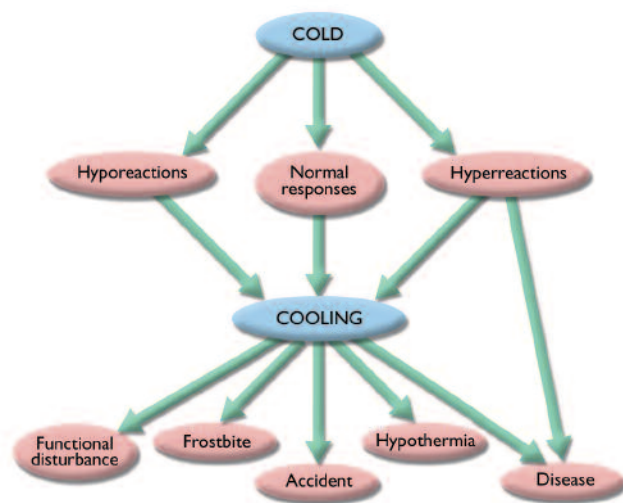
Human body heat balance depends on: the thermal
environment (air temperature, air velocity, air moisture,
and radiative heat gain from sun or artificial sources);
the thermal insulation of clothing; and the rate of physical
work producing heat via metabolic pathways (e.g.,
Parsons K., 1993). For a naked human at rest, the
thermoneutral air temperature is 27 ºC. In temperatures
above the thermoneutral zone, heat loss is increased by
sweating, and in lower temperatures, heat production is
increased by muscular work (up to about 1200 W) or by
shivering (up to about 500 W). By doing heavy physical
work, a naked human can survive at an air temperature
of about -5 ºC for several hours. The extreme limits of
behavioral temperature regulation depend on available
technology, but working at extreme low or high tempera-
tures is possible with special clothing. The removal of
body heat by air movement, and its practical application
in designing appropriate clothing, is known as the "wind-
chill" effect (Quayle and Steadman, 1998).


Fig. 15.6. Interactions between temperature and health.

The effects of heat balance are usually classified in terms of five levels: comfort, discomfort, performance degradation, health effects, and tolerance (Lotens, 1988). For an adequately clothed person initial cold problems start to appear at an ambient temperature of 10 ºC when fingers start to cool during light manual work. Even with heavy work, cold problems appear at between -20 and -25 ºC. For optimal manual performance, skin temperature is 32 to 36 ºC. Below a skin temperature of 13 ºC manual performance rapidly deteriorates. Marked changes in ambient temperature can increase or decrease cognitive performance or remain without effect. When effects are seen, cold particularly appears to affect the performance of complex cognitive tasks involving short-term or working memory (Palinkas, 2001).

Psychological, whole body, and local physiological acclimatization develops when the thermal environment is changed. Marked acclimatization can be developed within about ten days. In cold, the usual signs of acclimatization are blunted responses of the cardiovascular system (heart rate and blood pressure) and heat production (shivering). Cold-induced vasoconstriction in hands is also attenuated (e.g., Rintamäki, 2001). Heat acclimatization involves increased sweating and earlier onset of sweating.

For healthy active people a 5 to 10 ºC decrease in temperature is not expected to result in serious effects on the maintenance of body heat balance during outdoor work. Humans can compensate for a 10 ºC decrease by wearing additional clothing or by increasing metabolic heat production by 30 to 40 W/min. If the temperature of arctic or subarctic climates increases by 5 to 10 ºC, the climate would still be cool or cold, with cold temperatures still having more impact on human physiology than heat. More serious problems could occur under extreme conditions such as during the coldest winter months in arctic or subarctic climates, if ambient temperatures decrease or the cold season increases markedly in length. There is an upper limit to the thermal insulation of winter clothing. A decrease or increase in ambient

temperature, especially if the change is rapid, is a more serious threat for sick and/or elderly people than for healthy individuals capable of a physically active lifestyle.

15.3.2.2. Cold injuries

Cold-related injuries are immediate pathological consequences of cold exposure. As a consequence of direct or indirect effects of cold, the total injury rate may increase in relation to environmental cold exposure. The rate of slip and fall injuries, for example, increases with decreasing temperature. Increasing rates of slip and fall injuries are seen at temperatures of 0 ºC and below. Low temperature is often a secondary source of injury and may not be reflected at true frequencies in statistical records. Risk of unintentional injury is least at a temperature of about 20 ºC and increases with lower and higher ambient temperatures.

Injuries such as frostbite, hypothermia, and others are linked to body cooling. Cooling injuries occur most often during winter months, especially during the few coldest winter days and are also increased by wind speed. Cooling injuries show a strong relationship with temperature, i.e., the lower the temperature the more injuries occur. The majority of cooling injuries are freezing injuries (e.g., frostbite) (Taylor M., 1992).

Frostbite generally occurs on the most peripheral parts of the body (head, hands, feet). For the head, frostbite of the ears is almost twice as common as frostbite of the nose and cheek. Several areas of the body may be injured simultaneously. Mild frostbite most commonly occurs in the head region. Frostbite of the feet and hands frequently causes severe tissue damage and requires medical treatment or hospitalization. Young Finnish men reported a 2% annual incidence in frostbite over their lifetimes. Twenty-five percent was blister grade or more severe. In general, the incidence of frostbite varies annually from 0 to 27% among different outdoor occupations. Also, urban people experience more frostbite than rural people for the same thermal environments (Ramsey et al., 1983). Frostbites are comparable to burns in their immediate consequence. The immediate effect of frostbite can be a mild or more severe functional limitation of the injured area, requiring medical attention, and in some cases, hospitalization. The most common latent symptoms of frostbite are local hypersensitivity to cold and pain in the injured area, cold-induced sensations and disturbances in muscular function, and potentially excessive sweating. These latent symptoms may have negative impacts on occupational activities in 13 to 43% of cases. Permanent post-symptoms or invalidity commonly develop as a result of severe frostbite requiring hospitalization (Miller and Chasmar, 1980). Factors known to cause a predisposition to frostbite include cold-provoked white finger phenomenon, sensitivity to cold, diabetic vascular disease, psychiatric disorders, prior frostbite, older age, and tobacco smoking (Hassi and Mäkinen, 2000). Use of certain drugs or alcohol, "cold protective ointment" on the face, and inadequate clothing increase risk of frostbite during cold exposure

(Lehmuskallio, 1999). Accidents, fatigue, and poor nutrition are also associated with increased frostbite risk.

15.3.2.3. Cold-related diseases

Cold-related diseases are either caused by cold or are affected by cold exposure. The rate of cooling in different sites of the human body is also modified by individual factors like cardiovascular diseases, diseases of peripheral circulation, respiratory diseases, musculoskeletal diseases, and skin diseases.

Cardiovascular diseases

The higher incidence of cardiovascular events in colder regions and during winter is well known, and several mechanisms have been suggested based on increased blood pressure, hematological changes, and respiratory infections (Keatinge, 1991). Most investigations have used ecological data such as daily temperatures recorded at weather stations and mortality in the general population. Cause-specific mortality is the outcome measure most commonly used. Hospital discharge records, linked with out-of-hospital deaths, provide a powerful tool for detecting even weak effects of temperature. The association of coronary heart disease mortality and temperature is usually U-shaped, mortality being lowest within the range 10 to 20 ºC and higher either side. However, the temperature at which mortality reaches a minimum is lower in colder countries (Fig. 15.7). For example, in Yakutsk, Siberia, temperatures as low as -48 ºC had no effect on coronary mortality rates (Donaldson et al., 1998a; Näyhä, 2002).

The increase in mortality on the colder side is about 1% per 1 ºC decrease in temperature, but the increase on the warmer side may be very steep. The exact point of the minimum temperature and the magnitude of the effect vary between countries. In Finland, the winter excess mortality from coronary heart disease has leveled off over recent decades. The share of annual mortality from cardiovascular diseases due to cold is estimated at 5 to 20%. The detailed mechanisms by which cold is related to cardiovascular mortality, either directly or by respiratory infections or indirect effects of winter behaviors such as shoveling snow, have not been clarified. Cold exposure causes an increase in blood pressure and hemoconcentration resulting from fluid shifts, leading to coronary thromboses one to two days after cold exposure. Following the recent decline in influenza mortality, around half the excess winter deaths are now due to coronary thrombosis. These peak about two days after the coldest part of a long period of very cold weather. Around half the remaining winter deaths are due to respiratory disease, and these peak about 12 days after maximum cold days.

Cerebral vascular diseases

The association of temperature and cerebral vascular accidents is similar to that for coronary heart diseases with morbidity and mortality increasing with a decline
Fig. 15.7. Deaths from coronary heart disease and mean daily temperature in Finland, 1971–1995 (Donaldson et al., 2003).

in temperature. The pattern is often U-shaped, with some increase in numbers at warmer temperatures. The morbidity and mortality of stroke is usually lowest at temperatures of 15 to 20 ºC, however some variations exist. In northeastern Russia stroke mortality only increases at temperatures below 0 ºC (Donaldson et al., 1998b; Näyhä, 2002).

The gradient of cerebral vascular accidents against temperature is around 1% per 1 ºC decrease in temperature, as for coronary heart diseases. In Japan, the dose–response relationship was similar for intracerebral hemorrhages and cerebral infarctions, whereas in Finland a greater winter excess was observed in the incidence of intracerebral hemorrhage than for other forms of stroke, but no gradient relative to temperature has been reported. A change in temperature of at least a two-day duration is needed for stroke mortality to rise, and the time lag between the temperature change and the maximal increase in mortality is estimated at one to four days (Donaldson and Keatinge, 1999).

The long-term trends in the effect of temperature on stroke have not been determined, but the seasonal amplitude of stroke deaths in Finland has diminished since the 1920s. The proportion of stroke-related deaths attributable to the cold season was estimated at 13% in the 1960s, but had diminished to 9% by the 1990s. A British investigation which reported a decline of 57% in the stroke-temperature gradient between 1977 and 1994 also suggested that the effect of environmental temperature on stroke is being modified by other external factors (Donaldson and Keatinge, 1999).

Respiratory diseases

Common respiratory cold-related symptoms are watery rhinitis, and as a consequence of constriction of the bronchi, asthma-like symptoms which include wheezing, coughing, and breathing difficulties. Deaths related to respiratory diseases, primarily pneumonia, increase significantly during the winter months. Watery rhinitis is a physiological irritation response to cold air inhalation and is harmless.

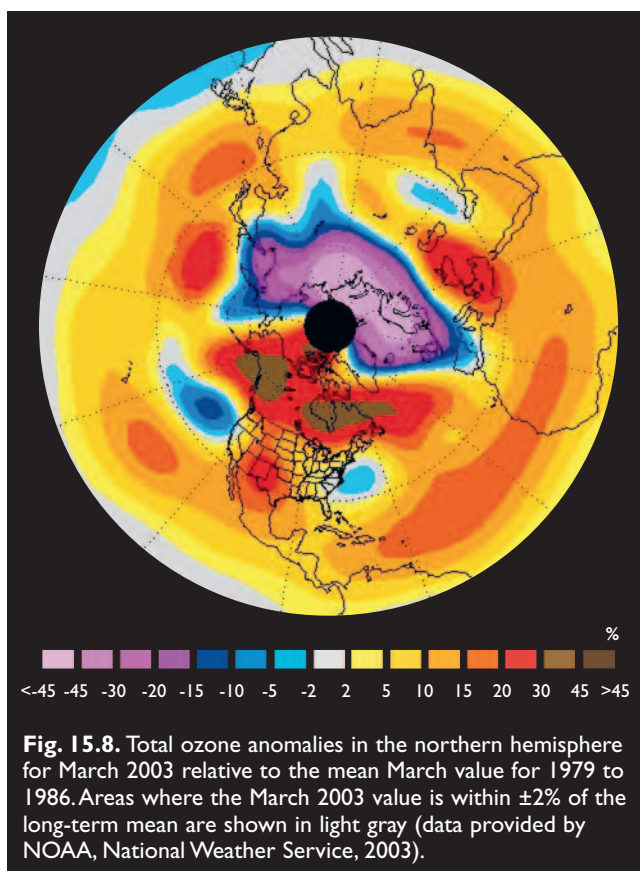
The prevalence of breathing problems provoked by exercise and/or cold weather is high among asthmatic subjects (81.6%) and significantly elevated among allergic subjects (45.1%) and people with chronic obstructive pulmonary disease (74.6%). For people with no known respiratory disease, the prevalence is 10.0%. The risk of chronic bronchitis and bronchitic symptoms at the population scale is elevated in outdoor workers in some populations, but is not elevated in regular recreational cross-country skiers, and the risk of developing asthma is not significantly elevated by regular exercise or work in cold climates. Constriction of the laryngeal area is a momentary reflex in response to cold air and is usually harmless. In very exceptional cases of the disease, known as cold urticaria, this phenomenon may be life-threatening. Air quality and behavioral choices such as smoking are also major influences on the incidence of respiratory diseases.

Peripheral circulatory diseases

The normal responses of the peripheral circulatory system to cold stress can be affected in individuals with vascular diseases. Thermal comfort and physical performance may be decreased and risk of cold injury may be increased. In advanced stages of peripheral arteriolosclerosis, blood vessels are narrowed. Further constriction caused by cold exposure may increase risk of frostbite. A reversible episodic constriction of the blood vessels in fingers and toes is a fairly common pathological response to cold exposure and is known as the Raynaud's phenomenon. Owing to the constriction of the blood vessels, the blood flow in fingers and toes is markedly reduced at temperatures colder than 10 ºC. Originally, Raynaud's phenomenon was described as episodic white fingers provoked by cold or other stress factors, together or alone. The population prevalence is 5 to 30% and is related to gender, age, and region of residence (Maricq et al., 1993). As a clinically significant condition, it has a reported prevalence of 2 to 6%. Cold exposure in a patient with the condition may result in a cluster of different symptoms caused by transient constrictions occurring in the circulation of the heart, lung, kidneys, or brains. The symptoms may vary widely and can include migraine headaches, chest pain, and possible visual effects.

Cold urticaria

The most familiar and common abnormal skin reaction related to cold exposure is cold urticaria. It is usually a chronic condition and is often provoked by some other physical agent. Symptoms usually occur locally on exposed areas of skin. They sometimes appear during cold exposure but more frequently appear when the skin re-warms after cooling and then disappear again after 20 to 30 minutes. Fifteen percent of the population is subject to symptoms at some stage and the annual average prevalence in Finland is 2 to 4%. Cold urticaria lasts from months to several years. Prevalence of hospitalization for severely affected patients is only around one in 4000. In cold urticaria, skin reaction to cold exposure is characterized by erythema, swelling, wheals, or papules.

Other symptoms on cold exposure can be more severe, such as vertigo, headache, nausea, vomiting, tachycardia, dyspnea, flushing, faintness, or rarely, life-threatening anaphylactic shock.


Musculoskeletal diseases and symptoms

There is limited scientific understanding of the relationship between musculoskeletal diseases and cold. Extensor tenosynovitis has been described with windy cold exposure in temperatures from 0 to -25 ºC (Georgitis, 1978). The increased incidence of tenosynovitis in female food industry workers was attributed to the low ambient temperature (Chen et al., 1991; Chiang et al., 1993). Local cold exposure in a frozen food factory was associated with a ten times higher incidence of carpal tunnel syndrome than in warm environments (Chiang et al., 1990). Symptoms of musculoskeletal diseases can vary, and include local or generalized feelings of pain and fatigue of muscles and joints. Low back pain, knee pain, and shoulder pain were significantly more common in cold storage workers than in a thermoneutral environment and were dependent on the duration of the work in the cold environment.

Cold-related immune effects

Cold temperatures and isolation can be immunosuppressive and, in humans who have over-wintered in the Antarctic, suppression of cell-mediated immunity is well documented (Ando, 1990; Muller et al., 1988; Tingate et al., 1997). The effect of sunlight-induced immunosuppression above (or concomitant with) this temperature/isolation induced immunosuppression remains to be determined.

15.3.2.4. Summary

Changes in the frequency or intensity of natural disasters or extreme weather events can have direct and indirect impacts on human health in the Arctic. In remote locations this is accentuated by a reduced capacity to respond to these events because of the isolated nature of the communities and the often limited health infrastructure present. The variability of such events is likely to increase with future climate changes. Changes in temperature have the potential to influence health in arctic communities in both negative and positive ways. With the low mean annual temperature in many arctic regions, the likelihood of heat events having large health impacts on the general population is low. However, the impacts of these events on individuals with respiratory problems and other conditions can be serious. Fewer colder days associated with winter warming in some regions may actually have several positive health impacts. Impacts of cold temperature are well known and increases in the length or magnitude of extreme cold periods in some regions may have significant negative impacts on the general population, especially for individuals with conditions making them more susceptible to such exposure. Under any climate change scenario, tem-

Fig. 15.8. Total ozone anomalies in the northern hemisphere for March 2003 relative to the mean March value for 1979 to 1986. Areas where the March 2003 value is within ±2% of the long-term mean are shown in light gray (data provided by NOAA, National Weather Service, 2003).

Fig. 15.9. Average total ozone over the Arctic (63° to 90° N) in March. 1971 and 1972 data are from the BUV instrument on the Nimbus-4 satellite; 1979–1993 data are from the Total Ozone Mapping Spectrometer (TOMS) on Nimbus-7; 1994 data are from the TOMS on Meteor-3; 1996 data are from the SBUV/2 on NOAA-9; 1997 data are from the TOMS on the Earth Probe satellite. (http://www.cmdl.noaa.gov/star/arcticuv2.html).
perature will continue to influence the health of arctic populations both directly and indirectly.

15.3.3. UV-B radiation and arctic human health

Stratospheric ozone loss has been observed during the winter/spring months over most of the Arctic since the early 1990s. Losses of up to 40% have been recorded in Scandinavia and Siberia, and in Canada, sporadic losses of 10 to 20% or more have been reported. The daily total ozone level in March 1997 at Point Barrow (71.3° N) in Alaska was about 6% below the previous ten-year average, and on 17–18 March 1999, Barrow experienced record low ozone levels for that location in March.

During winter and spring 2001/02, the mean March stratospheric ozone levels show a 5 to 15% loss of ozone compared to the average March value for 1979 to 1986. The 2002/03 winter also had low total ozone values over parts of the Arctic. The decrease was greater than for the previous two winters, but not as great as in the 1990s. During the winter months of 2002/03 (December, January, February, and March) parts of the Arctic, mainly but not limited to Siberia and Scandinavia, had levels up to 45% lower than comparable values for the same area in the early 1980s (NOAA National Weather Service, unpubl. data, 2003). Recent data indicate widely diverse ozone losses continuing throughout the year. Figure 15.8 shows the March 2003 anomalies for stratospheric ozone relative to the average March values for 1979 to 1986.

Figure 15.9 shows the large decline in average total ozone values in March over the Arctic (63º–90º N) during the 1990s. McKenzie et al. (1999) presented some of the strongest data to date regarding the relationship between ozone loss and increased levels of UV-B radiation. Although their data are for the southern hemisphere the same relationship is highly likely to occur in the Arctic. The data, which reflect ozone levels for the austral summers between 1978/79 and 1998/99 and UV-B radiation levels for the austral summers between 1989/90 and 1998/99 at 45º S (Fig. 15.10), provide strong evidence for increases in UV-B radiation levels in areas where baseline levels were already high, suggesting that man-made perturbations to the ozone layer are occurring as predicted (see also Chapter 5).

UV-B related human health effects include increases in the incidence of skin cancer, potential effects associated with increased suppression of the immune system including weakened resistance to some types of infectious disease (Sleijffers et al., 2002), and increased incidence of cataracts as well as changes in Vitamin D_3 production in the skin (IASC, 1995). In the Arctic, increases in UV-B radiation may also interact with other environmental stressors such as chemical pollutants, cold temperature, isolation, and viral illnesses in some populations (IASC, 1995). The rest of this section describes potential UV-B related health effects.

15.3.3.1. Immunosuppression

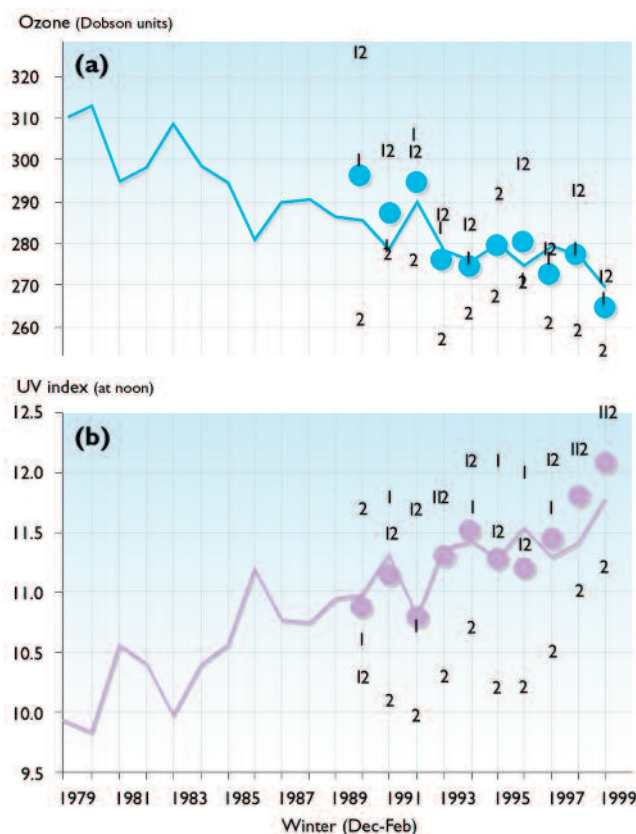
Ultraviolet-B radiation can initiate a selective down regulation of cell-mediated immunity in mammals, including humans. It is speculated that this may be a natural regulatory mechanism, selected through evolutionary pressure, to prevent autoimmune attack on sunlight-damaged skin (De Fabo and Noonan, 1983). The unusu-


Fig. 15.10. Association between (a) ozone loss and (b) increased levels of UV-B radiation (Mackenzie et al., 1999).

al feature of UV-B-induced immunosuppression is that it redirects cell-mediated immunity to sensitizing antigens from an up or "effector" type response to a down or "suppressor" type response. These antigens can include chemical, viral, and tumor antigens (Noonan and De Fabo, 1992). Significantly, skin pigmentation is not an efficient protection factor against UV-B induced immune suppression. Immunosuppressive effects of UV-B radiation play an important role in UV-B induced skin cancer by preventing the destruction of highly antigenic skin cancers by the immune system (De Fabo and Kripke, 1979, 1980).

An in vivo wavelength dependence study by De Fabo and Noonan, (1983) for immune suppression of contact hypersensitivity in mice has identified a light-absorbing substance, residing on skin, as *trans*-urocanic acid (UCA). The *cis* structure of UCA (*cis*-UCA) formed upon absorption of light by *trans*-UCA, is known to cause immunosuppression in humans similar to that in mice caused by UV-B radiation (van Strien and Korstanje, 1995). In addition to sunlight modulation of cell-mediated immunity, which may involve susceptibility to certain infectious diseases (Sleijffers et al., 2002), *cis*-UCA may be important for arctic populations for another reason. A recent report indicated that a binding receptor for *cis*-UCA has been identified as the neurotransmitter 5-hydroxytryptamine, or 5HT (Serotonin) (Nghiem et al., 2002; Walterscheid et al., 2002). Lack of sunlight is known to play a role in mood disorders (Nilssen et al., 1997),

among other factors (Näyhä et al., 1994), in arctic populations (Nilssen et al., 1999). Future studies are needed on the role of UCA in human immunity, as well as on mood disorders linked to sunlight deprivation. Box 15.2 describes the action spectra and biological amplification of UV radiation.

Genetically determined susceptibilities to UV-induced immunosuppression have been shown to exist and appear to be controlled by several interacting *Uvs* genes involving autosomal and X-linked genes. Such an interaction for UV-immunosuppression had not been described previously and may be unique for this mechanism (Noonan and Hoffman, 1994). A genetically determined high susceptibility to UV-induced immunosuppression may be an important risk factor for UV-related human diseases not just in arctic populations but in other populations as well.

15.3.3.2. Skin cancer

Immunosuppressive effects of UV-B radiation play an important role in UV-induced skin cancer by preventing the destruction of highly antigenic skin cancers by the immune system (De Fabo and Kripke, 1979, 1980). There are three main types of skin cancer. Two tend not to metastasize and are known as basal and squamous cell carcinoma, and are often referred to collectively as non-melanoma skin cancer. The third type, which shows a higher mortality, and which can metastasize aggressively, is malignant melanoma of which several subtypes exist (Fears et al., 1976; McGovern et al., 1973). It should be noted however that any potential increase in skin cancer incidence related to reflectance from snow is likely to be mitigated by the projected decrease in snow cover.

There is much experimental evidence of a clear connection between sunlight exposure and non-melanoma skin cancer, and which implicates UV-B radiation as a carcinogen (Armstrong et al., 1997; Fears et al., 1976; Parsons P. and Musk, 1982). A relationship between sunlight and malignant melanoma, while less clear, is considered a near certainty (Armstrong and Kricker, 1993; Berwick, 2000; Bulliard, 2000; Fears et al., 1976; Jemal et al., 2001; Mack and Floderus, 1991). Epidemiological evidence indicates that sporadic or intermittent sunlight exposure can be a very important factor in malignant melanoma development, especially in childhood (Autier et al., 1997). But not all sunburn leads to melanoma, as other predisposing factors are needed. The molecular mechanisms underlying the relationship between malignant melanoma and exposure to UV radiation, particularly wavelength specific mechanisms, such as the importance of UV-B radiation, as opposed to UV-A radiation are, at present, unclear. To help clarify these mechanistic pathways, recent developments include, among others, the genetic engineering of a transgenic mouse capable of producing melanoma tumors following UV radiation of neonatal animals. These tumors show a striking similarity to human melanoma (Noonan et al., 2001). Once the active waveband for melanoma induction is identified, an

Box 15.2. Action spectra and biological amplification of UV radiation

Photobiological responses are by definition wavelength dependent. However, to compare the biologically-inducing activity of the many spectrally different sources available, from sunlight to sun tanning lamps, it is necessary to consider differences in wavelength efficiency in initiating the biological response, whether it is skin cancer, sunburn, photosynthesis, or immune suppression. In order to make such comparisons, it is necessary to calculate, and then deliver "biologically effective" doses from the optical source. Differences in wavelength efficiency can be accounted for by using an appropriate wavelength-dependence or "action spectrum". An action spectrum describes the relative efficiency of radiation at different wavelengths to produce a given effect. Health effects experts, for example, rely upon action spectra to provide information regarding which wavelengths in the full spectrum of sunlight or the full spectrum of artificial sunlamps cause sunburn, or DNA damage (Sutherland, 1995; Young et al., 1998), or immune suppression (De Fabo and Noonan, 1983). Once experimentally derived, the action spectrum can be multiplied by the spectral output of any given source. In the case of sunburn, the International Commission on Illumination action spectrum for erythema (McKinlay and Diffey, 1987) is used to calculate the UV Index, a measure of sun burning effectiveness used worldwide (Long, 2003).

Action spectra are also useful in determining increases in biologically effective UV radiation doses due to ozone depletion, known as the "radiation amplification factor" (RAF), and how these increases in UV-B radiation result in "biological amplification" for a given response. For example, to predict changes in skin cancer incidence as a function of stratospheric ozone depletion, two processes are necessary. First, the increase in biologically effective UV-B radiation that results from an ozone loss of 1% must be determined, i.e., the RAF. Second, the ratio of the percentage change in biological effect to the proportional change in biologically effective irradiance – the BAF – needs to be determined. Thus, the total amplification factor for the biological impact is a product of the two: amplification factor = RAF × BAF. More detailed information on ozone depletion, skin cancer, and RAF/BAF determinations is reported by Moan et al. (1989), Jones (1992), and Strzhizhovskii (1998).

In addition to providing a weighting function to determine biologically-effective doses, action spectra are useful for helping to identify the initial light-absorbing photoreceptor responsible for triggering a light-driven biological response (De Fabo, 1980; Noonan and De Fabo, 1993). Such information can help direct further research on a given photobiological response (De Fabo and Noonan, 1983).

action spectrum can be constructed. A skin cancer action spectrum has been used to predict increases in non-melanoma skin cancer by increased UV-B radiation resulting from ozone destruction between 1979 and 1994 (Slaper et al., 1996).

In the Arctic, skin cancer rates are in general low. This is due primarily to the low UV-B radiation levels relative to equatorial regions. Also, skin cancer is rare in arctic indigenous populations consistent with findings elsewhere that skin pigmentation is protective against skin cancer. A recent study, however, involving Danes working in Greenland and cancer risk indicated an elevated risk of melanoma in females. A role for excessive UV radiation exposure in this regard has been suggested (Nielsen L. et al., 1997). With increasing numbers of non-indigenous people living in the Arctic, the incidence of melanoma and non-melanoma skin cancer must be carefully monitored in both groups. Some indigenous groups in the Arctic are reporting evidence of increased UV-B radiation exposure and are experiencing skin rashes and burns for the first time. They report a sense that the "sun is hotter" (Fox S., 2002; Furgal et al., 2002; see also Chapter 3).

> *The sun burns us easily, it was not very hot in the past.* Kuujjuaq, man aged 62 as quoted in Furgal et al., 2002

> *The sun was not that hot in the past. Nowadays, it's really hot. My skin burns when I'm out for a while. Sometimes, we stay indoors in a shack.* Kuujjuaq, man aged 70 as quoted in Furgal et al., 2002

15.3.3.3. Non-Hodgkin's lymphoma

Certain epidemiological evidence suggests a link between non-Hodgkin's lymphoma and sunlight exposure (Langford et al., 1998; Zheng and Owens, 2000). This is suggested to be via the immunosuppressive effects of UV-B radiation (Langford et al., 1998; McKenna et al., 2000; McMichael and Giles, 1996; Zheng and Owens, 2000). A correlation between the occurrence of skin cancer and the occurrence of non-Hodgkin's lymphoma has also been described (Cliff and Mortimer, 1999). However, in contrast to non-melanoma skin cancer, non-Hodgkin's lymphoma does not show a latitudinal gradient in the United States, suggesting that UV-B radiation may be a cofactor rather than a primary causative agent of this disease. Danish women working in Greenland are reported to show an excess of lymphatic malignancies, which raises the question of a role for excess UV-B radiation (Nielsen L. et al., 1997). Autoimmune diseases such as Type-I diabetes and multiple sclerosis may also have an immunosuppressive connection with UV-B radiation

(Staples et al., 2003). The continued reports regarding correlations between health problems and UV radiation indicate the need for further investigation in relation to ozone loss over the Arctic (McKenna et al., 2003; Okada et al., 2003).

15.3.3.4. Cataract

Cataract is a major cause of blindness. In 2002, there were an estimated 180 million people worldwide who were visually disabled. Between 40 and 45 million people are blind (http://www.who.int/pbd/en). Epidemiological reports and experimental studies indicate that cataract formation is a complicated process with many associated risk factors. The precise mechanism of action is not known although UV-B radiation is very strongly implicated and associations with latitude and climatically different countries have been reported (Hockwin et al., 1999; Katoh et al., 2001; Sasaki H. et al., 2000; Sasaki K. et al., 1999; Taylor A. et al., 2002; Taylor H., 1989; West, 1999). Furthermore, a recent action spectrum indicated that after correcting for corneal transmittance, the biological sensitivity of the rat lens to UV-B is at least as great at 295 nm as at 300 nm. After correcting for transmittance by the atmosphere, UV-B at 305 nm is suggested to be the most likely wave band to damage the rat lens (Merriam et al., 2000).

Several types of cataract exist with a varying degree of association with sunlight (Hockwin et al., 1999; Katoh et al., 2001; Sasaki H. et al., 2000; Sasaki K. et al., 1999; West, 1999). Published evidence tends to support the concept that cortical cataract is more likely to be related to UV-B radiation (Hockwin et al., 1999; Katoh et al., 2001; Sasaki H. et al., 2000; Sasaki K. et al., 1999; West, 1999). Another study, however, suggests the opposite when lifetime cumulative UV-B radiation exposure and exposure after teenage years are considered (Hayashi et al., 2003), underscoring the need for further study including detailed wavelength or action spectrum studies on cataract. The importance of dietary factors and cataract also requires further research (Taylor A. et al., 2002; Valero et al., 2002; Wegener et al., 2002).

15.3.3.5. Vitamin D

Vitamin D (calciferol) is a fat-soluble vitamin. It is present in food, but can also be made in human skin after exposure to UV-B radiation from the sun. In general, skin synthesis provides most of the vitamin D to the body (80 to 100%; Glerup et al., 2000) and with adequate sunlight exposure, dietary vitamin D may be unnecessary (Holick, 2001).

Many factors can affect vitamin D production such as season, latitude, age, skin color, time spent outdoors, and sun angle. Few foods contain significant amounts of vitamin D that can act as a substitute for sunshine exposure. Fish with a high fat content, such as sardines, salmon, herring, and mackerel are excellent sources of

vitamin D. Other important sources are meat, milk, eggs, and fortified foodstuffs. Fortified foodstuffs however, may not be sufficient to preclude the need for sunlight exposure. In one study it was reported that dark-skinned, veiled, pregnant women, their infants, and elderly in residential care had the highest vitamin D deficiency of subjects studied (Nowson and Margerison, 2002). This suggests that vitamin D deficiency may be a bigger risk factor in populations worldwide when other factors reducing exposure to sunlight are considered e.g., arctic populations during long, dark winters. A balance is thus needed between sunshine exposure and risk of excessive sunlight leading to skin cancer or other UV-B related health effects, or insufficient sunlight exposure and hence vitamin D deficiency for diseases such as rickets and certain non-skeletal diseases (Fahrleitner et al., 2002; Pasco et al., 2001).

Vitamin D exists in several forms, each with a different activity, and is involved in a large variety of biological functions, including regulatory functions (for a comprehensive review of vitamin D see Feldman, 2003). Briefly, the liver and kidney help convert vitamin D to its active hormone form (calcitriol). For example, in skin vitamin D is produced from UV-B-induced photo-conversion of 7-dehydrocholesterol (7-DHC; pro-vitamin D). Vitamin D then undergoes hydroxylation to calcidiol ($25\text{-}OHD_3$) in the liver and becomes the major circulating form, and then to calcitriol (vitamin D_3 hormone; 1alpha $25\text{-}(OH)_2D_3$) in the kidney. 1alpha, $25\text{-}(OH)_2D_3$ is carried systemically to distal target organs where it binds to a vast array of nuclear receptors to generate its appropriate biological response. Vitamin D appears, therefore, to be involved in various aspects of fundamental cell regulation.

The major function of vitamin D is to maintain normal blood levels of calcium and phosphorus. Vitamin D aids calcium absorption, helping to form and maintain a strong skeletal structure. Without vitamin D, bones can become thin, brittle, soft, or deformed. Vitamin D prevents rickets in children and osteomalacia in adults, which are skeletal diseases that result in defects that weaken bones. A recent study reports for the first time a link between UV-B radiation exposure and calcitriol synthesis in human skin (Lehmann et al., 2003).

Given the six months of darkness in winter followed in spring/summer by potential excess exposure to UV-B radiation due to ozone depletion, studies in arctic communities on UV-B induction of vitamin D in liver and kidney and vitamin D hormone in skin are of high priority.

15.3.3.6. Other factors

Pollutants

Many types of pollutant have been identified in arctic biota and the arctic environment, including polyaromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs),

and heavy metals (AMAP, 2002). There is some evidence of interaction between UV-B radiation and chemical pollutants. For example, aquatic organisms that have ingested UV-B-absorbing PAHs have been shown to exhibit phototoxic effects following exposure to UV-B radiation (Huovinen, 2000). A number of persistent organic pollutants, including PCBs, are immunologically damaging even without exposure to UV-B radiation. At present there is little information on the potential for the combined effects of these agents or on immunosuppression from exposure to UV-B radiation alone. In view of such findings and the high levels of persistent organic pollutants in areas of the Arctic, research is required on the combined effects of UV-B radiation, PAHs, and PCBs.

Dietary factors

Diet may also be important in UV-B effects in arctic populations. Experimental evidence shows that UV-related immunosuppression in mice can be increased by increasing dietary histidine (Reilly and De Fabo, 1991) and correlates with a modulating increase in *trans*-urocanic acid (De Fabo et al., 1997). High levels of dietary fat have also been demonstrated to enhance UV-induced immunosuppression in experimental systems (Black et al., 1995) and may be a factor in arctic populations as well as high histidine levels in some species of fish (Suzuki et al., 1987) and seal (Hoppner et al., 1978).

Viral interactions

Activation of viruses by UV radiation is well-documented (Ando, 1990; Coetzee and Pollard, 1974; Tingate et al., 1997; Zhang et al., 1999; Zmudzka et al., 1996). Indigenous populations appear predisposed to cancers such as nasopharyngeal and salivary gland cancer (Nielsen L. et al., 1997). These cancers are thought to be associated with the high viral load in these populations, and genetic factors also appear to be involved. Salivary gland cancer has been linked to UV radiation exposure in several studies on non-arctic populations (Nielsen N. et al., 1996) although a latitude gradient has not been demonstrated. UV-B radiation may be a co-factor. Herpes simplex virus (HSV) is found in all races, cultures, and continents. The virus affects 80 to 90% of the world's population. Most people have herpes simplex as cold sores or genital herpes. In experimental animal models UV-B radiation was shown to release immune inhibition on HSV expression and lead to HSV manifestation. A similar effect may occur in the human population (Taylor J. et al., 1994). Whether enhanced levels of UV-B radiation due to ozone depletion will exacerbate HSV or other viral infections in the arctic population remains to be determined.

Infectious diseases

The emergence of new infectious diseases and the re-emergence of old infectious diseases is also an issue in the Arctic (Butler et al., 1999). Given an association

between the lowering of resistance to some infectious diseases by UV-B induced immunosuppression in experimental animal systems (Sleijffers et al., 2002), plus a lowering of the cellular immune response against hepatitis B vaccination in humans by urocanic acid (Sleijffers et al., 2003; section 15.3.3.1), attention to increases in infectious diseases as a consequence of increased exposure to UV-B due to ozone depletion is of high priority.

15.3.3.7. Summary

A lack of detailed information on human health effects due to increased exposure to UV-B radiation in the Arctic precludes an evaluation of risk assessment at present. Skin cancer appears to be a low risk phenomenon in the Arctic particularly in indigenous populations. However, given the long-term likelihood of ozone loss and increased levels of UV-B radiation, it is not clear how long this low risk will be maintained. Indigenous and non-indigenous populations should both be monitored routinely for skin cancers, cataracts, and precursors to such conditions. The effect of UV-B induced immune suppression, alone or in combination with arctic stressors and pollutants, on human or animal populations is also unknown. The implications of increased UV-B exposure on the incidence of viral and infectious diseases in arctic populations need to be addressed. Also, understanding of the interactions between UV-B radiation, pollutants, and traditional diets requires significant effort in the future. Population effects related to UV-B health effects following stratospheric ozone depletion is a major research topic for the Arctic as the stratospheric ozone layer will remain vulnerable for the next decade or so even with full compliance with the Montreal Protocol (UNEP, 2003).

15.4. Potential impacts of indirect mechanisms of climate change on human health

In addition to direct impacts of climate-related changes on human health, human health in northern communities is affected by a number of indirect impacts. These refer to those health consequences resulting from indirect interactions mediated via human behavior and components of the environment that have changed or are changing with local climate. These indirect effects include critical impact mechanisms such as social and mental stress related to changes in the environment or lifestyle which are related to changes in local climatic regimes. They include such things as effects on diet (decreased subsistence/cultural food species abundance and/or availability) as a result of climate-related impacts on wildlife species or environmental factors influencing indigenous peoples' access to these resources (e.g., ice distribution, land stability, weather predictability); effects on health as a result of changed access to good quality drinking water sources; effects on rates of diseases resulting from climate effects on sanitation infrastructure; and changes in human disease incidence associated with climate impact on zoonotic diseases.

15.4.1. Changes in animal and plant populations

Climate change can have dramatic effects on the numbers and distribution of species in an ecosystem and these changes may have significant social, cultural, and health effects on indigenous human populations. All ecosystems are a dynamic equilibrium of species and climate is one of the most important factors in this delicate balance. Climate changes, even subtle changes, may shift this balance to favor some species, stress other species sometimes to the point of extinction, and allow new species to enter the system. Other chapters of this report address the significant and sometimes dramatic affects of climate change on species. Infectious disease agents of plants, animals, and humans are integral components of all ecosystems and may increase, decrease, or spread into new regions as a result of climate change. The dynamics of these changes and how they may affect human health are described in this section.

15.4.1.1. Species responses

Since the late 19th century, global temperatures have risen by an average of 0.6 °C with the increases more pronounced at higher latitudes and higher elevations (IPCC, 2001). A review of 143 studies involving range distributions of nearly 1500 species showed that over this period 80% had shifted their ranges toward the poles (Root et al., 2003). These shifts are likely to be greater in polar regions where the temperature increase has been greater.

Increased warming from the mid-1970s to the mid-1990s is thought to have been the major reason for a rise in salmon numbers in the Bering Sea and North Pacific (Weller et al., 1999). Salmon is an important traditional food for many indigenous people and an important economic asset in the Bering Sea and North Pacific. However, the increased temperatures also had some adverse health effects. The warming caused increased productivity at all levels of the food chain including increased numbers of those algae which cause toxic red tides and paralytic shellfish poisoning (Patz et al., 2000; Weller et al., 1999). Extreme environmental events such as flooding which washes nutrients into coastal waters could also increase the occurrence of paralytic shellfish poisoning.

The warming trend that caused high salmon numbers in the North Pacific and Bering Sea may also have been the major factor responsible for the dramatic reduction in Alaska salmon since 1997 (Mathews-Amos and Berntson, 2002; Weller et al., 1999). Higher water temperatures may have increased salmon metabolism to levels that could not be sustained by existing food sources and spawning salmon were often smaller than normal. A reduction or disappearance of traditional food species may result in indigenous populations switching from a traditional diet to less healthy diets; such dietary shifts are associated with an increased prevalence of chronic diseases such as diabetes, heart disease, and cancer among northern populations (Bjerregaard and Young, 1998). Health effects related to extreme economic hardship could also follow a decline in traditional food species.

Climate change often creates opportunities for species to move into new regions. Species may colonize a region from an adjacent area, through migration or through accidental or intentional transport by humans. In Alaska, recent warming has increased average growing degree-days by about 20% (USGCRP, 2000). This has had a significant impact on the ecosystems there. Sustained warming on the Kenai Peninsula in south-central Alaska encouraged a spruce bark beetle infestation and the largest tree death in North America. Northern expansion of the boreal forest has favored the steady advance of beaver in northern and western Alaska. Beaver make dramatic alterations in surface water and fish habitat. They may also expand the range of Giardia, a parasitic disease of beaver that can infect many other animals and humans. An expansion in the range occupied by beaver has also been reported by indigenous people in other regions of the Arctic (Furgal, 2002; Krupnik and Jolly, 2002).

> *We see moose now, and never did before. We see them more and more each year. We've seen them up as far as the bay north of here (Nain).* Nain, hunter aged 43; in Furgal et al., 2002

> *It was maybe twenty years ago that we saw the first beaver track ever up in the bay (Webb's Bay, north of Nain)…we didn't know what it was.* Nain, hunter aged 46; in Furgal et al., 2002

It is not unusual for a few individuals of a migratory species to deviate from normal pathways and arrive in a new region. Every year Alaskan bird watchers are thrilled at "exotic" Asian species that visit local bird-feeders. If the new ecosystem is favorable the species can become permanently established. Climate change may create favorable habitats in regions that could not previously be inhabited. Successful establishment of a new species alters the ecosystem and impacts upon other species (Root et al., 2003). Accidental introductions arising from human activities may also result in colonization. There is concern in Alaska about species transported into the region when ships discharge ballast waters. Climate change may create conditions in the marine environment that are favorable to species introduced in this manner. The marine ecosystem is vital to subsistence food users and the economies of Alaska and other northern regions. The introduction of competing species or diseases of existing species could be catastrophic for the fisheries and indigenous communities of the Arctic.

15.4.1.2. Infectious diseases

Infectious disease agents are part of any ecosystem and are also affected by climate change. Stresses posed by climate change may increase the susceptibility of plants and animals to disease agents causing both the rates of infection and severity of infection to increase. High inci-

dences of diseases and die-offs were reported during recent El Niño–Southern Oscillation events (Mathews-Amos and Berntson, 2002; Weller et al., 1999). Climate warming during these events has been associated with sickness in marine mammals, birds, fish, and shellfish. Disease agents associated with these illnesses have included botulism, Newcastle disease, duck plague, influenza in seabirds, and a herpes-like virus epidemic in oysters. Diseases that attack species forming habitat for other species, such as seagrass, are also affected and can have devastating environmental impacts. If such effects arise following the temporary temperature shifts associated with El Niño–Southern Oscillation events, then it is likely that temperature changes arising from longer duration climate change will be associated with an increased occurrence of diseases and epidemics.

Species expanding into new regions will expose resident species to any disease agents they take with them. This is the case for beaver and Giardia. Giardia is a waterborne disease, and beaver dams increase the surface water habitat that promotes the spread of the parasite to other animals such as caribou and humans. Infected caribou may also increase the spread of the parasite as they migrate to other parts of their range. Other waterborne diseases are also likely to become a greater risk due to beaver-engineered surface water changes especially in areas where people use untreated surface water.

Species that benefit from climate changes are likely to increase in numbers and create more hosts for disease agents. Expansion of host species into new regions and the reformulation of ecosystems increase the probability of spread to new host species. Species that have not been exposed to a new infectious disease agent are often extremely susceptible to the infection. The catastrophic epidemics in indigenous North Americans following the introduction of smallpox, tuberculosis, influenza, and many other infectious diseases after European contact are such examples.

The West Nile virus is a recent example of how far and fast a disease agent can spread after colonizing a new region. The virus was first identified on the east coast of North America in 1999 and by the end of 2003 had spread to all lower 48 states except Washington and Oregon in the United States and seven of 13 Canadian provinces and territories (CDC, 2003; Health Canada, 2002). Nearly 9000 human cases and over 200 deaths occurred in the United States in 2003. West Nile virus is primarily a disease of birds that is transmitted by mosquitoes.

Infected migratory birds are responsible for the spread of the West Nile virus into a region, with mosquitoes responsible for the spread of the virus to other birds (and other animals and humans). Even though the virus originated in tropical Africa it has adapted to many North American mosquitoes and so far to over 130 species of North American bird, some of which migrate to the Arctic (CDC, 2003). Mosquito species known to transmit the virus are also found in the American Arctic.

Climate has always posed a barrier for insect-borne diseases but climate change and the extremely adaptive nature of the West Nile virus may favor continued northerly expansion. The extent of future expansion and the possibility of transmission to the Arctic remain to be seen. Some northern regions, such as Alaska, have initiated a West Nile virus surveillance program (ADHSS, 2000). If the virus does reach Alaska, migratory birds could carry it to the massive population centers of China and South Asia.

Zoonotic diseases are diseases of animals that can also be transmitted to humans. Rabies is a classic example. Rabies infects many wild and domestic animals which may then spread the disease to humans usually from saliva through a bite. In the Arctic, rabies is most often carried by fox and conditions which favor increased fox numbers can lead to rabies epidemics and to human cases. Other arctic zoonotic diseases that could be influenced by climate change include botulism, paralytic shellfish poisoning, tularemia, brucellosis, echinococcus, trichinosis, and cryptosporidium. Botulism spores occur in marine sediments and the intestinal tracts of animals and fish (Chin, 2000). In Canada and Alaska outbreaks have been associated with seal meat, salmon, and salmon eggs. Also, warmer temperatures are reported to influence traditional fermentation processes (for the preparation of fermented meat – *igunaq*) which are related to increased cases of botulism in Nunavik (Furgal et al., 2002). Alaska has established a paralytic shellfish poisoning surveillance program in areas where the algae responsible for the production of the toxin occur. Climate warming may favor the spread of these species to new regions.

The mechanisms by which climate change affects disease agents and their hosts vary. Warmer temperatures may allow species with a low rate of infection, such as brucellosis in caribou or echinococcus in voles, to survive in larger numbers increasing the number of susceptible hosts and infected animals. Disease agents that survive in soil and water may benefit by warmer temperatures. Climate change may stress host species reducing their resistance and increasing rates of infection. Host species may enter new regions bringing disease agents with them. Continental cross-over from the Americas to Eurasia and from Eurasia to the Americas, as with the West Nile virus and influenza, is also possible and perhaps even more likely with climate change.

Diseases that infect important traditional and economic species can also affect human health. Indigenous groups throughout the circumpolar north have reported a variety of abnormal conditions and diseases in salmon over recent years (Krupnik and Jolly, 2002). Of increasing concern are diseases of farmed salmon or other fish that enter Alaskan waters via ballast waters and then spread to wild salmon. Reduced salmon consumption by indigenous peoples in favor of less healthy foods could lead to increased levels of diabetes, cardiovascular disease, and cancer.

Diseases that could threaten arctic ecosystems and populations following climate change include those that already exist in the Arctic and those moving in from more southerly areas (see Box 15.3). The Arctic could also be a source of disease agents. For example, if West Nile virus reaches Alaska it could easily jump to Asia via established bird migration routes. Diseases of livestock and poultry could also expand through arctic transmission routes. Expansion of disease agents into new environments, in new hosts, and via new vectors encourages new adaptations through natural selection. These could include changes in virulence and resistance and so result in more dangerous strains.

Influenza is an example of a disease that could be disseminated by arctic bird species to populations in other parts of the world. Bird influenza viruses serve as a genetic reservoir for other animal influenza strains including those that infect humans (Webster, 2002). Migration can spread these viruses to other species and humans. Influenza is not the stuffy nose, headache, and upset digestive tract that people equate with flu. In each of the 11 epidemics of the last three decades influenza killed 20 000 to 40 000 Americans. The Spanish flu strain of 1918 to 1919 killed more than 20 million people. In the 1998 influenza epidemic in Hong Kong a third of all diagnosed cases died (Tam, 2002). Fortunately the outbreak was small and did not spread (see Box 15.4).

Extreme events, such as droughts, floods, and storms (see section 15.3.1), are also linked to changes in ecological systems resulting in bacterial proliferation and impacts on the availability of safe drinking water (Mayer and Avis, 1997). Abnormal rainfall events can trigger mosquito-borne disease outbreaks, flood-related disasters, and depending on existing water infrastructure and systems used in northern communities, contamination of the water supply with human and animal waste. Human health depends on an adequate supply of potable water. If climate change affects the availability of freshwater supply, sanitation systems and the efficiency of local sewage systems will also be affected. Changes in rainfall patterns may also force people to use poorer quality sources of drinking water, potentially increasing the risk of bacterial and other contamination. This is particularly important for those communities in which significant numbers of individuals still rely on traditional sources of drinking water. All these factors could result in an increased incidence of diarrheal diseases.

15.4.1.3. Summary

Arctic climate change is likely to have profound effects on living things and thus human health, both in northern communities and throughout the world. When traditional food species are affected, dietary patterns may shift to less healthy food choices and diseases such as diabetes, cardiovascular disease, and cancer are likely to increase.

Box 15.3. Zoonotic diseases, climate change, and human health

Zoonotic diseases are infectious diseases of animals that can be transmitted to humans. Humans can be infected by these diseases a number of ways. Rabies, tularemia, and many others are transmitted by direct contact with infected animals. Others such as Giardia are shed into the environment and humans are infected following environmental exposure such as consuming contaminated water. The transmission of other diseases may be more complex. Humans are exposed to the West Nile virus from mosquitoes that were infected from birds harboring the virus. Many zoonotic diseases exist in arctic host species. Climate change may influence the spread, proliferation, and transmission of these diseases to humans through a variety of means.

- Tularemia is a bacterial disease of many mammals including rabbits, muskrats, and beaver, as well as humans and could become an increased threat in stressed animals or by animals expanding into new ranges. Tularemia may cause a variety of symptoms in humans. The pneumonic form has a 30 to 60% fatality rate.
- Rabies epidemics in the Arctic are linked to the fox and the cyclical increases in fox populations (Dietrich, 1981). Climate changes which increase rodent and rabbit populations could be a factor in rabies epidemics.
- Brucellosis is a bacterial disease of many hoofed animals and carnivores. It can cause a wide variety of symptoms in humans and the fatality rate is around 2% in untreated cases (Chin, 2000). Bison, caribou, reindeer, foxes, and bears can carry the disease (Dietrich, 1981). Climate changes that affect the distribution of these species could increase or decrease the risk from brucellosis.
- Echinococcus is a tapeworm parasite of animals and humans. The natural cycle involves foxes or dogs and rodents. Humans are an incidental host when they ingest eggs passed by dogs or foxes. The parasite develops invasive destructive cysts in the abdominal cavity and the infection is often fatal (Chin, 2000).
- An arctic strain of trichinella occurs in marine mammals such as walrus (Dietrich, 1981) and accounts for trichinosis outbreaks in some northern regions (e.g., Nunavik). Climate warming that reduces numbers of marine mammals or eliminates them from their current range may decrease the threat and occurrence of human cases of trichinella.
- Cryptosporidium is a protozoan parasite of many animals and humans (Chin, 2000). Some recent epidemics involved contamination of community water sources. Climate changes could favor the spread of the parasite to arctic communities that consume untreated surface water.

Changes in the traditional food lifestyle are also likely to affect human health through changes in social and cultural activities. Changes that affect commercially important species and so increase or decrease local income can also affect human health. Infectious diseases of plants, animals, and humans are also affected by climatic changes. Owing to the indirect nature of these influences, predictions of their likelihood are not possible; however, the potential impacts on human health related to these changes clearly warrant further attention.

15.4.2. Changes in the physical environment

15.4.2.1. Ice and snow

Climate warming scenarios project changes in sea-ice distribution and ice thickness in the Arctic (see Chapter 4). The direct human health effects of a reduction in ice thickness include injuries and death. Travel over increasingly thin ice for fishing, hunting, or recreation activities becomes increasingly dangerous. Mortality statistics show that accidents cause a significant number of deaths in some Inuit populations (e.g., Hodgins, 1997). Inuit in northern Canada report a decrease in ice extent and thickness during key traveling and hunting times in some communities (Furgal et al., 2002; Nickels et al., 2002).

The indirect health effects related to these changes are associated with marine productivity. Sea ice has a major influence on primary production and the ecology of species such as seals, walrus, and polar bear (see Chapter 9). Ice algae are a major source of food for a wide range of zooplankton and crustaceans. A reduction in sea-ice extent would reduce the substrate available for the ice algae and so reduce the food source for the ice-associated zooplankton and crustaceans. Greater melting of sea ice would decrease the salinity of the water column and the rate of the vertical flow which brings nutrients up from

deeper waters (Conover et al., 1986), further reducing the productivity of the phytoplankton. A decrease in primary productivity would affect the crustacean and fish populations upon which seal populations rely (Welch et al., 1992). Also, populations of seals and walrus, which require sea ice for breeding and pupping, may decline as ice-covered areas recede (Maxwell, 1997). This would affect polar bear populations as seals are their major food supply. Polar bears in Hudson and James Bay are particularly vulnerable in this respect. Some species could be extirpated or become extinct if the Arctic Ocean becomes ice-free for much of the year (Maxwell, 1997). Arctic foxes, normally scavenging polar bear kills, may be forced to increase predation on nesting birds in the summer (Welch et al., 1992).

Cooling, as is projected for some arctic regions, could have both positive and negative impacts on indigenous food security. During the major cooling of the Arctic around AD 1400 to 1700, the Inuit are thought to have adapted by hunting ringed seals (*Phoca hispida*) which became more plentiful as the sea ice extended (McGhee, 1987). Similarly, changes in the timing, amount, and composition of snow can affect the health of arctic residents as it influences their abilities to hunt, travel, and access traditional foods at certain times of the year. The changes projected in ice and snow under the various climate change scenarios (see Chapter 4) could have potential impacts on individual and community social health and well-being (see Box 15.5).

> …*and all of a sudden we had a storm and everyone was lost, years ago you'd get the good snow for snow houses but now, you wouldn't be able to make one [snow house] if you had to.* Nain, hunter aged 49; in Furgal et al., 2002

Many villages in the Arctic are connected to other settlements only by sea or air. Because air service to the vil-

Box 15.4. Climate change, arctic birds, and influenza

Wild birds host many species of virus including influenza. Birds may serve as the source of genetic material or of new influenza strains that could infect humans.

The role and mechanism of wild birds in this process is now better understood (Snacken, 1999; Tam, 2002; Webster, 2002). Numerous influenza strains are found in wild water birds. The bird–flu relationship is very stable and most infections even with multiple strains cause no symptoms. Many millions of these birds with their associated influenza viruses inhabit the Arctic. Peak numbers in birds and viruses occur in autumn and move south during migration. As the huge flocks move southward influenza strains circulate and recombine within the migrating birds and infect domestic birds and swine along the flyways. Influenza in domestic species brings the viruses closer to humans. The right combination of strains in domestic animals could be the source of a new human strain and a global epidemic. Climate change that favors nesting success, expansion to new ranges, and intermingling of bird species could contribute to this process.

The Spanish flu strain of 1918 to 1919 that killed more than 20 million people was thought to have emerged from a swine or bird strain (Snacken, 1999). The Asian flu strain of 1957 and the Hong Kong strain of 1968 may have been the product of human and bird strains. The 1997 to 1998 influenza epidemic in Hong Kong originated in poultry (Tam, 2002). That epidemic, even though it was small with only 18 confirmed cases, was especially alarming because six of these cases resulted in fatalities.

lages in many regions is irregular, villages are otherwise isolated for two to five weeks every autumn and spring when there is too much ice in the water to go by boat but not enough ice to go by dog sledge or snowmobile. During this period, hunting, fishing, and travel between villages is limited by means other than plane and there is often reduced provision of goods to local stores, and reduced availability of fresh meat or vegetables in some communities. For short periods, the weather can become so stormy that normal everyday activities within the village are difficult. This increased sense of isolation is reported to be associated with increased incidences of interpersonal conflict, depression, and other forms of social stress (Furgal et al., 2002).

15.4.2.2. Permafrost

Permafrost is very sensitive to temperature fluctuations. The top layer of permafrost, known as the active layer, thaws in summer and freezes again in winter. A warming of 4 to 5 °C would cause more than half of the discontinuous permafrost zone in Canada to disappear. Under such a scenario, the boundary between the continuous and discontinuous permafrost zones is expected to shift northward by hundreds of kilometers and the active layer in the discontinuous zone is projected to increase to twice its current depth (Maxwell, 1997). The uneven pitted terrain which results can severely affect animal activities and can damage or destroy the ecosystems based on the permafrost (Osterkamp, 1982, 1994). Several impacts of thawing permafrost have already been observed in Alaska (IASC, 1997).

- Destruction of trees and reduction in areas of boreal forest.
- Expansion of thawed lakes, grasslands, and wetlands.
- Destruction of habitat for caribou and terrestrial birds and mammals.

Box 15.5. Climate change and traditional food security

Traditional foods collected from the land, sea, lakes, and rivers are important sources of health and well-being to many indigenous communities. Such foods continue to contribute significant amounts of protein to the total diet and help individuals to meet or exceed daily requirements for several vitamins and essential elements (AMAP, 2003; Blanchet et al., 2000; Kuhnlein et al., 2000; Van Oostdam et al., 1999). Historically, by eating all animal parts, northern indigenous diets provided the nutrients and essential elements required to sustain life in this harsh climate. Such items are still important today as they contribute, for example, nearly 50% of the weekly protein, iron, and vitamin A intake in Nunavik women under 45 years old (Jetté, 1992) and nearly 50% in Labrador Inuit (Lawn and Langer, 1994). Components of the Inuit diet, particularly omega-3 fatty acids in fish oils, have been shown to provide protection against arteriosclerosis and ischemic heart disease (Bjerregaard et al., 1997) and some cancers. Also, marine species are the main source of selenium in northern diets; an antioxidant and a known anticarcinogen that may also help protect individuals from mercury toxicity (Blanchet et al., 2000). In addition to the substantial nutritional benefits, traditional foods provide many cultural, social, and economic benefits to individuals and communities.

Climate changes may affect the consumption of traditional foods by northern people through a variety of means. Impacts may occur via changes in access to food sources, for example by:

- a change in the distribution of important food species;
- the unpredictable nature of weather, as this can influence the possibilities for hunting or fishing;
- low water levels in lakes and streams, the timing of snow, and ice extent and stability, as these can influence access to hunting locations and key species; and by
- a shorter winter season and increased snowfall (two effects of a warmer climate), as these may decrease the ability of northern people to hunt and trap (Maxwell, 1997).

Climate changes may influence the availability and health of traditional food species via:

- impacts on critical components of their diet (e.g., climate impacts on vegetation may influence caribou health and abundance);
- impacts on their ability to forage and survive critical seasons (e.g., deeper snow and changes in freezing rain incidents can negatively affect the ability of caribou and reindeer to forage in winter);
- warming, as this may increase the exposure of some species to insects, pests, and parasites; and via
- temperature changes as these may influence migration and breeding patterns.

The impacts of a decline in the proportion of traditional foods consumed by northern peoples are significant. Shifts away from a traditional diet toward a more western diet, higher in carbohydrates and sugars, are associated with increased levels of cardiovascular diseases, diabetes, vitamin-deficiency disorders, dental cavities, anemia, obesity, and lower resistance to infections. Both climate warming and cooling are as likely to impact on aspects of indigenous food security in the future as they have in the past.

• Clogging of salmon spawning streams with
  sediment and debris.

Such impacts could further affect traditional food
sources (e.g., caribou, salmon) and the related activities
(e.g., hunting, gathering, fishing) (AMAP, 2003).

15.4.2.3. Summary

Through changes in the timing and conditions of ice
formation, stability, and break up, the amount and
timing of snow, and the stability of critical land (e.g.,
permafrost) in the regions used by indigenous commu-
nities, climate change can result in significant negative
impacts on the health of community residents.
According to some indigenous communities these
changes and their effects are already occurring. Such
changes are likely to continue to affect the safety of
land- and water-based travel, and availability and access
to traditional food species by arctic residents and will
thus continue to challenge the health of indigenous
communities in the future.

15.4.3. Built environments in the north

Infrastructure promotes safe and healthy community
environments and provides access to health-related serv-
ices. In northern regions, housing provides protection
against harsh environmental conditions and, with ade-
quate ventilation, a healthy living environment.
Sanitation facilities are needed to prevent the spread of
disease and are increasingly important when population
densities are high, or when even small populations are
fixed in one location. In small remote communities
transportation is often necessary to gain access to health-
care or emergency services. It is likely that climate
change will adversely affect infrastructure and housing
throughout the Arctic.

15.4.3.1. Sanitation infrastructure

Unsafe drinking water combined with inadequate sani-
tation and hygiene is listed sixth in the top ten health
risk factors leading to disease, disability, and death
worldwide (WHO, 2002). The provision of high quality
water can protect against chemical constituents and
waterborne diseases such as hepatitis, gastroenteritis,
typhoid, cryptosporidiosis, and giardiasis (American
Public Health Association, 2001; Smith D. et al.,
1996). Sufficient quantities of water are required for
personal hygiene, cleaning, and laundry. Epidemics of
otherwise commonly preventable diseases such as hepa-
titis A, hepatitis B, bronchitis, otitis media (a serious
ear infection), impetigo, and meningitis in remote
Alaskan communities are often attributed to poor
sanitation. Alaskan Native villages with inadequate
sanitation systems accounted for more than 72% of
596 reported cases of hepatitis A in Alaska in 1988
(US OTA, 1994). The spread of diseases caused by con-
taminated drinking water or inadequate sanitation is a
concern for communities throughout the world.

Sanitation facilities can consist of individual facilities such
as septic systems or pit privies (outhouses) or communi-
ty facilities such as organized haul systems or pipeline
networks. The level of health in a community depends on
the type of sanitation facilities (US OTA, 1994). Water
hauled by individual residents may be safe at the point of
collection, but might become contaminated in the con-
tainers used for transport and storage. Closed haul sys-
tems (sealed containers) or piped utilities can reduce the
potential for contaminating water supplies or human
contact with sewage (US OTA, 1994). Sanitation facili-
ties can include different levels of service. In the most
basic form, water and wastes are hauled to and from the
residence by hand. Providing a community water and
wastewater haul system can raise the level of service.
Such systems provide greater amounts of water for sani-
tation purposes and therefore improve the level of com-
munity health. Piped utility systems provide the highest
level of service and commensurate health benefits.
The level of sanitation service provided to arctic commu-
nities varies. For example, few Russian arctic communi-
ties are served by piped systems, while virtually 100% of
Norwegian arctic communities have piped systems or
adequate individual facilities. In Canada, Greenland, and
the United States, the level of service provided to com-
munities varies substantially from region to region.
In some cases, communities must support utility opera-
tion via local user fees. In other cases, the cost of utility
operation is supplemented by sources outside the com-
munity. In the Arctic, where residents may rely heavily
upon subsistence and where economic conditions are
often strained, even minor increases in costs may nega-
tively affect utility operation and maintenance.

15.4.3.2. Water supply systems

Water supply systems include a water source, storage
facility, and distribution system. Water sources contami-
nated by biological, chemical, or mineral constituents
may require treatment to render the water supply safe
for human consumption. In the United States it is esti-
mated that contaminated drinking water causes more
than 900 000 people to become ill and up to 900 to die
each year (American Public Health Association, 2001).
In 1993, inadequate water treatment in one city caused
an outbreak of approximately 403 000 illnesses, 440 hos-
pitalizations, and 50 deaths (Craun et al., 2002).

Water supplies are required for personal hygiene, clean-
ing, drinking, and cooking. Owing to the labor involved,
when water is hauled individually it is used for drinking
and cooking and tends to be used sparingly for hygiene
and cleaning (Smith D. et al., 1996). In more sophisti-
cated sanitation systems, water is used to transmit
human waste from residences through pipelines or via
haul tanks to the point of treatment and/or disposal.

Source

Water sources exist as surface supplies or groundwater
wells. The highest quality source with adequate quantity

available to the local community is typically used. Sources with significant levels of contaminants require more complex treatment and are undesirable due to increased treatment costs and complexity.

Arctic surface water sources include streams, rivers, lakes, tundra ponds, or man-made impoundments that capture snow and rain. Surface water sources require some form of treatment to ensure that the water is safe for drinking owing to the potential for contamination by pathogens (US EPA, 1992). Groundwater sources generally have less risk of contamination by pathogens. Naturally occurring organic or inorganic substances can exist in surface water and groundwater supplies. These contaminants are often removed early in the treatment process to avoid the possibility of transforming them – through chemical reactions with disinfectants – into potentially dangerous byproducts.

Although high quality arctic groundwater sources exist, permafrost often restricts the volume these aquifers can produce. Alternatively, there might be a sufficient volume of groundwater to meet a community's needs but it may be so highly mineralized that it requires sophisticated and costly treatment.

Climate change can cause water sources to become inadequate in volume or unfit in quality in a number of ways. For example:

- Groundwater supplies can be reduced by less frequent precipitation. Intense but less frequent rainstorms limit aquifer recharge by the majority of the water being lost to runoff.
- Drought or short intense storms can affect surface water impoundments. The water supply in small impoundments or lakes can be depleted during long dry periods. Intense storms may cause watersheds to release water too rapidly creating high but short-duration flows and with most of the precipitation being lost to runoff.
- Coastal communities can experience increased levels of salinity, dissolved solids, or other contaminants in groundwater due to a climate change induced sea-level rise (Linsley et al., 1992). The groundwater may become brackish and unfit for human consumption.
- Flooding of coastal areas by storm surges may become more frequent and severe. Tundra ponds or lakes, located near the coast, can become contaminated by seawater with their water becoming brackish and thus unfit for human consumption.
- Levels of salinity and bromide may increase in river intakes due to rising sea levels. The saline wedge can penetrate farther upstream potentially contaminating river intakes with seawater (Smith O., 2001).
- Intense storms can create high runoff rates that may exceed the design capacity of a water diversion or dam overflow structure. This may result in damage or the complete loss of the facility.

- Thawing permafrost may also damage water diversion or dam structures. As permafrost thaws, structures founded on frozen soil can become unstable. This may compromise the ability of the structure to impound or divert the necessary volumes of water.
- Flooding caused by ice jams in northern rivers often occurs in the spring or early summer when riverbanks are frozen. Flooding of rivers in late summer or autumn is rare. Intense rainstorms that cause flooding when soils are thawed will accelerate riverbank erosion and increase the potential for damage to adjacent structures.
- Northern communities often have limited economies – many based on subsistence. Contaminated water sources or damaged intake structures will require repair, modification, or replacement. If resources are not available for repairs or facility replacement, residents may be forced to use an unsafe water supply.

Treatment

Water treatment systems are designed to remove contaminants and inactivate pathogens. Designs differ, and are based on the properties of a water source. Climate change can result in a decrease in the quality of a water source which can then overwhelm the treatment system. The treated water may be safe for consumption but unpalatable due to taste, smell, or color. This can result in residents seeking alternative sources that are untreated and potentially unsafe. Climate change can adversely affect water treatment systems in a number of ways. For example:

- Rising sea levels can contaminate groundwater or surface water sources. A consequent rise in bromide concentrations may increase the formation of dangerous byproducts during disinfection (Singer, 1999). The process required to treat a water source contaminated by bromide is complex and costly; operation and maintenance of such systems may be prohibitively difficult and expensive for small, remote communities.
- Intense rainstorms can increase turbidity, pathogen, and organic contaminants in a water source. A substantial increase in these contaminants can exceed the ability of a water treatment system to produce safe and palatable water. High levels of suspended material can overwhelm a filtration process and reduce the effectiveness of a disinfectant to inactivate pathogens. Increased levels of organic contaminants can overwhelm a treatment process and increase the formation of dangerous disinfection byproducts (Singer, 1999).
- Warming weather and longer dry periods can cause more frequent and severe algal blooms in lakes or ponds used as a surface water supply. Algae may clog water treatment filters and so reduce the ability of the system to meet demand. The presence of algae can also increase the formation of disinfec-

tion byproducts or cause foul tastes and odors making the water unpalatable (Linsley et al., 1992; Singer, 1999).

Distribution

Water distribution in northern communities consists of self-haul, community-haul, or piped utility systems. Self-haul systems require minimal infrastructure because water can be hauled by foot, sled, or small all-terrain vehicle (Fig. 15.11). Community-haul systems use larger haul containers, which require larger vehicles and therefore substantial all-weather access ways. Self-haul and community-haul systems both require convenient access to the bulk treated water storage tank to be viable.

Access roads and boardwalks must be maintained in passable condition for haul systems to operate (Fig. 15.12). The road, bridge, or boardwalk must be structurally sound and capable of supporting relatively heavily loaded vehicles under repetitive daily cycles of operation.

Piped utilities rest on aboveground supports or are buried below ground. The more desirable and conventional belowground installation requires thaw-stable soils. When thaw-stable soils do not exist, piped utilities are usually constructed aboveground to minimize the potential for thawing of the permafrost and subsequent loss of foundation support for the structure (Fig. 15.13).

When a piped distribution system is used, pipelines must remain sound to ensure the water supply remains safe for human consumption. A breech in a pipeline can allow contamination of the water to occur within the distribution system (Geldreich, 1992). In 1989, contamination of the water supply caused by a pipeline breech in Cabool, Missouri, resulted in 243 people becoming ill and four dying (Fox K., 1993).

Often, arctic piped distribution systems continuously circulate water for freeze protection. Loss of water in a distribution system during cold weather can result in loss of circulation and complete freeze failure of the system (Smith D. et al., 1996).

Large structures such as water storage tanks cannot accommodate significant movement of the foundation. Movement of the foundation or loss of foundation support can cause a breech in the shell of a water storage tank, potentially rendering the facility unusable.

Climate change, can adversely affect water distribution systems in many ways. For example:

- Flooding caused by storm surges or heavy rainstorms can damage roads, boardwalks (Fig. 15.14), water storage facilities, and aboveground pipelines. In some areas, floodwaters can include ice, which may substantially increase floodwater damage.
- Roads, boardwalks, pipelines, and water storage facilities can be adversely affected by erosion. Riverbank erosion may accelerate during late season flooding. Coastal communities may experience accelerated erosion along shorelines due to thawing permafrost, severe storms, rising sea levels, or reduced periods of sea-ice cover.
- Frozen seas protect shorelines and reduce the generation of waves created by severe winter storms. Indigenous people report that the extent and duration of sea-ice cover is changing (e.g., Furgal et al., 2002; Krupnik and Jolly, 2002; Nickels et al., 2002; see Chapters 3 and 6).
- Thawing permafrost can result in the loss of foundation support for aboveground or belowground pipelines, water storage facilities, access roads, or boardwalks. Loss of foundation support for a pipeline can damage the facility and allow contamination of the water supply (Geldreich, 1992). Damage to storage facilities, access roads, or boardwalks can render a water distribution system inoperable.

15.4.3.3. Wastewater systems

Wastewater systems transport human waste from residences, provide treatment, and dispose of effluent. Improper methods of collecting, treating, or disposing of human waste have been attributed to numerous

outbreaks of infectious disease (US OTA, 1994). In Sweden, 3600 people became ill at a ski resort through a cross connection between a drinking water reservoir and a sewage pipeline (Fewtrell and Bartram, 2001). In Alaska, between 1972 and 1995 more than 7000 cases of hepatitis A were reported to the Epidemiology Section of the Health and Social Services Department. The method of transmission was via the fecal–oral route. Inadequate sewage disposal in many remote communities was cited as the cause.

The level of service provided by wastewater collection, treatment, and disposal systems varies throughout the Arctic. In some remote Alaskan villages, residents use small buckets to collect human waste. Buckets are then carried by hand to central disposal points where wastes are dumped into receptacles (Fig. 15.15), or carried directly by the resident to sewage disposal facilities. This is often referred to as a "honey bucket" haul system. A plastic liner is often used to line the bucket and contain the waste. Hauling wastewater from residences by hand is the most unsanitary form of collection and represents the lowest level of wastewater service.

Improved levels of service include pit privies and holding tanks. Pit privies are frequently used when homes are scattered and soil and groundwater conditions are favorable. Holding tanks are used when homes are located in close proximity, or when soil conditions or high groundwater makes septic systems infeasible. Holding tanks are sited at residences and emptied by a community-owned or commercial pumping service. The holding tank size in a particular community is determined by economics and access. Because many villages have narrow roads and boardwalks, large vehicle access is limited and holding tank volumes are typically small (Fig. 15.16). Thus, the amount of water available for personal hygiene and cleaning is minimal. Piped utilities provide the highest level of service. Flush toilets are normally used in piped systems, and water supplies and wastewater removal systems can provide ample water for personal hygiene, cleaning, laundry, or other sanitation needs.

Collection

Wastewater collection systems are designed to minimize the potential for human contact with sewage. Disease transmission can occur in populations where collection systems are inadequate and contact with wastewater is not controlled (IHS, 1999a; Schliessmann et al., 1958). Failed collection systems can discharge human waste to the environment, contaminate water supplies, and transmit disease via human contact. Many of the effects of climate change on water distribution systems also apply to wastewater collection infrastructure. Roads must remain in passable condition throughout the year for haul systems to operate; pipeline integrity must be maintained for piped wastewater collection systems to function properly.

Treatment and disposal

Wastewater treatment for small remote arctic communities is generally limited to simple systems. Mechanical treatment methods, such as aeration, are not typically used due to cost and complexity of operation (Smith D. et al., 1996).

In the Arctic, individual wastewater treatment facilities include pit privies and septic systems. Community facili-

Fig. 15.17. Lagoon waste washed through fence by storm surge flooding, Kipnuk, Alaska (photo by Brian Aklin).

ties typically include earthen lagoons, tundra ponds, septic tanks with ocean outfalls, and septic tanks with drainfields. When communities are located near water and favorable soils exist, drainfields are placed within the thaw bulbs of rivers or along seashores.

Wastewater treatment and disposal systems are designed to ensure wastewater remains separate from the water supply, human contact with waste does not occur, and the potential for vector transport is limited.

Climate change can adversely affect wastewater treatment and disposal systems in a number of ways. For example:

- Flooding caused by storm surges or swollen rivers can adversely affect wastewater lagoons, tundra ponds, bunkers, pit privies, or septic systems. Floodwaters may enter these facilities and spread partially treated waste throughout communities or into water supplies (Fig. 15.17).
- Riverbank or shoreline erosion can damage wastewater facilities located along seashores or within the thaw bulb of a river. Erosion can also intercept wastewater lagoons and tundra ponds.
- The warming of ice-rich permafrost beneath lagoon dikes can cause the loss of structural support. As dikes settle, a breech may occur resulting in the discharge of human waste into the environment. In such circumstances, increased maintenance – at a minimum – is required to sustain operational wastewater volumes and treatment efficiencies.
- However, warming weather and longer summers can also increase biological activity in wastewater lagoons and natural tundra ponds used for treatment. This increase in biological activity can improve treatment efficiencies resulting in increased treatment capacity and potentially delaying the need to expand or replace facilities due to community growth.

15.4.3.4. Solid waste systems

Solid waste collection and disposal in the Arctic is performed with relatively conventional methods. Recycling, incineration, and baling facilities are rare and generally limited to larger communities. Collection in very small communities is typically by self-haul. Larger communities often use community-haul systems, which are preferred because wastes are more likely to be discarded in proper locations.

Solid waste disposal sites in the Arctic are generally frozen. Landfill wastes are often inadvertently mixed with snow due to winter operations and later covered with soil. Therefore wastes remain stable as long as materials remain frozen.

Many of the effects of climate change on water and wastewater systems also apply to solid waste collection infrastructure. Landfill access routes must remain passable for collection and disposal to occur. Flooding and erosion of solid waste landfills can spread waste, contaminate water supplies, and transmit disease through human contact. As frozen solid waste materials thaw, they can release contaminants into the environment through runoff.

15.4.3.5. Building structures

Critical requirements for housing in the Arctic include efficient and dependable heating and adequate ventila-

Fig. 15.18. Access road damage by coastal erosion, Shishmaref, Alaska (photo by Tony Weyionanna).

tion. Northern economies are often limited and houses are typically small, and so less costly to construct and heat. Such conditions may result in overcrowding. Also, building envelopes are usually tightly constructed to reduce heat loss and minimize heating costs. This combination of overcrowding and poor ventilation can lead to poor indoor air quality and potentially unhealthy living conditions.

Indoor air pollutants dangerous to health include mold, radon, tobacco smoke, carbon monoxide, and chemical emissions from household products and furnishings. Adverse short-term health effects of poor indoor air include asthma, hypersensitivity pneumonitis, and humidifier fever. Long-term health effects include respiratory disease, heart disease, and cancer.

Climate change can result in the destruction of housing via flooding and erosion, through loss of foundational support due to thawing permafrost, or by severe storm damage. Lost housing can cause further overcrowding, respiratory illness, and mental stress in small communities.

Health service buildings within remote communities offer quick access to basic health care and emergency services. When these structures are damaged by climate change, community health care is disrupted.

Transportation infrastructure

Transportation infrastructure provides access to health services located outside remote communities. Emergency transport of individuals from northern communities, usually by medical evacuation, to sites where comprehensive health services exist is critical. Infrastructure such as airstrips, roads (Fig. 15.18), and docks can be damaged by climate change. This damage can limit access to critical health care and emergency services.

15.4.3.6. Summary

The potential effects of climate change include increased variability in precipitation, reductions in the extent of sea ice, and climate warming and cooling. These changes can increase the frequency and severity of river and coastal flooding and erosion, drought, and degradation of permafrost. Such changes are very likely to impact on arctic infrastructure and housing.

Water sources may be subject to saltwater intrusion and increased contaminant levels, which may overwhelm treatment processes and jeopardize the safety of drinking water supplies. The quantities of water available for basic hygiene can become limited due to drought and damaged infrastructure. The incidence of

Box 15.6. Infrastructure, climate and public health: Shishmaref, Alaska

Recent studies indicate reductions in sea-ice thickness and shorter periods of sea-ice cover in Alaska. These climatic changes have increased shoreline erosion of Shishmaref, an Iñupiat village of 560 people located on Sarichef Island in the Chukchi Sea.

Archaeological finds indicate centuries of human habitation in Shishmaref. Villagers state that erosion has been accelerated by soils no longer frozen, limited sea-ice cover, and increasingly violent weather. During the winters of 2000/01 and 2002/03, erosion caused the bluff line to recede more than 12 meters, destroying structures and forcing other homes to be moved. Several other communities in the region, including Kivalina, Wainwright, and Barrow, face similar challenges related to coastal erosion.

Shishmaref uses two different haul systems for water and wastewater transport. One system consists of small water and sewage holding tanks within homes that are filled and emptied by small motorized haul vehicles operated by the community. Remaining residents haul their own water and use a community-operated honey bucket haul system for waste disposal. The community's water source is a rain/snow catchment impoundment located near sea level. Water is treated by a simple unaided sand filtration system with activated carbon enhancement.

Recent storms in Shishmaref have prompted evacuations, washed away a number of boats used for subsistence, and destroyed buildings and roads. Erosion is threatening the sewage lagoon and the village sanitation system, and local officials are concerned that seawater has contaminated the community's water source (Anchorage Daily News, November 23, 2003, Severe Storms Pound Shishmaref).

The destruction, property loss, threatened sanitation systems, and realization that the community will ultimately have to be moved is creating significant stress within the community. In summary, climate-related changes in Shishmaref will have both short-term and long-term effects on human health.

Coastal erosion damage, Shishmaref, Alaska (photo by Curtis Nayokpuk).

disease caused by contact with human waste can increase when sewage is spread by flooding, damaged infrastructure, or inadequate hygiene. Damaged infrastructure increases repair costs and further stresses fragile arctic economies.

The positive effects of climate change include reduced heating costs for buildings and pipelines. Treatment efficiencies in wastewater lagoons may also improve due to warmer water temperatures resulting from longer periods of warm weather. This increased efficiency may delay the need to expand natural wastewater treatment systems as local populations grow. As an example, Box 15.6 summarizes the links between infrastructure, climate, and public health in Shishmaref, Alaska.

15.4.4. Contaminants

Human and ecosystem health in the Arctic is affected by the accumulation of heavy metals and biologically persistent man-made compounds of industrial and agricultural origin, known as persistent organic pollutants (POPs). These contaminants are mostly generated at lower latitudes and transported by various natural mechanisms (termed contaminant pathways) to the Arctic. They then enter the arctic food chain, and are ultimately consumed by human residents who are often highly dependent on wildlife for food.

15.4.4.1. Human health effects

Health effects of chronic low-level exposure to POPs and heavy metals, such as lead, mercury, and cadmium, are, in general, incompletely understood. An assessment on this topic was published recently by AMAP (2003). Several points require emphasizing:

- in terms of low-level chronic food-borne exposure, pregnant women, the developing fetus, and the developing infant are the most sensitive stages of human life;
- the exposure is to a mixture, never a single compound, making assignment of cause and effect very difficult;
- toxicological models and wildlife studies suggest that neurodevelopment, growth, immunological development, and endocrine function are the most likely targets for effects from exposure;
- sensitivity to these compounds varies widely in wildlife and laboratory species, and is not always useful in predicting the toxicity of tissue levels in humans;
- the developmental effects potentially attributable in human infants exposed to these compounds can also be caused by many other exposures, confounding study results;
- arctic communities are often small, making statistically significant sampling difficult;
- long-term studies are further complicated by difficult access to remote communities for follow-up; and

- the arctic marine subsistence diet is rich in antioxidants such as selenium, omega-3 fatty acids, and other micronutrients. Selenium has the potential to mitigate the toxicity of mercury.

15.4.4.2. Major transport pathways

Major contaminant transport pathways include winds, ocean currents, and river outflow, all of which are affected by climate. Important mechanisms within the Arctic also affect contaminant transfer, such as surface ice movement, thawing of permafrost and glaciers, season length, changes in freshwater lakes, and the partitioning of chemical compounds between gas, liquid, and solid phases. Migratory species, which spend significant parts of their life cycle at lower latitudes, can accumulate these contaminants and bring them into the Arctic. Also, increased levels of human activity in the Arctic, including maritime transport, represent a potential mechanism for contaminant transport and release. Each of these mechanisms is reviewed in this section within the context of potential impacts on human health. It must be understood that all these pathways, and their impact on transport, have the same limitations as climate models: (1) it is difficult to detect trends, due to short instrumental records, and (2) linking change in the various pathways to climate change, and predicting their effect on each other is poorly understood in many cases. A more complete discussion on this topic was published recently by AMAP (Macdonald et al., 2003).

Season length

The length of time air masses remain at, or above, critical temperatures influences the extent to which an organic contaminant can volatilize and remain easily within the gas phase, or attached to airborne particles. Air mass movements can be rapid and cover long distances. With the projected increase in season length, contaminant movement could significantly increase, both into and out of the Arctic. Season length, by its effect on ice melt, the active layer of permafrost, periods of ice-free river flow, and longer growing periods has the major mediating influence on contaminant movement into, out of, and within the Arctic (Macdonald et al., 2003).

Atmospheric transport

Atmospheric circulation in the Northern Hemisphere is influenced by atmospheric pressure. Established patterns of pressure variation, including the Northern Hemisphere Annual mode, often referred to as the Arctic Oscillation (AO) have major influence on surface wind (Wallace and Thompson, 2002).

The AO, while a major influence on arctic climate, is thought to account for only 20% of variance in atmospheric pressure (see Chapter 2). Short (5- to 7-year) and longer term (50- to 80-year) variations in the sea-

level atmospheric pressure fields, possible contributions from greenhouse gas warming, and the lack of long-term instrumental records make interpretation of AO variations since the 1960s difficult (Fyfe, 2003; Wang and Ikeda, 2001). Major winds into the Arctic fluctuate in intensity, duration, and to some extent, direction based on atmospheric pressure fields.

Various forms of precipitation, including snow and rain, act to remove contaminants from transporting air masses, and add them to land, surface ice, snow, and surface water. Increasing precipitation as a result of climate change could result in increased levels of contaminant deposition (Li et al., 2002).

Winds are the major source of mercury to the Arctic, mostly in its metallic gaseous form (AMAP, 2004). Loss of ozone in the upper layers of the atmosphere allows increased levels of UV-B radiation to reach the earth's surface in the Arctic. This initiates a complex mercury–halide interaction changing mercury to reactive gaseous mercury, which is easily removed from the atmosphere and taken up by the ecosystem in the early spring during the intense growth period. This atmospheric removal of mercury, termed a mercury depletion event, is most prominent during the period of "polar sunrise" in spring. The combination of possibly increased transport of gaseous mercury, less atmospheric ozone to block UV-B radiation, earlier ice-free periods along the Arctic Ocean shoreline, and abundant supplies of bromine and chlorine salts, could impact upon food web and human mercury accumulation. Extreme events might also increase rates of transport and contaminant deposition (see Fig. 8.22).

Ocean currents

Contaminant transport by ocean currents occurs primarily at the surface (Morison et al., 1998) and the largest input is from the North Atlantic between Greenland and Norway, with a smaller input from the North Pacific via the Bering Sea. A significant input from freshwater occurs via rivers entering the Arctic Ocean. The AO and season length influence these inflows.

A large volume of water and ice exits the Arctic Ocean via the Canadian Archipelago, carrying with it suspended and dissolved contaminants brought into the Arctic by wind, rivers, and ocean currents. Climatic conditions favoring increased ocean current transport to the Arctic Ocean would potentially expose all human residents, but might expose those of the Canadian Archipelago, as well as those of West Greenland and eastern Labrador, to higher levels.

Sea ice and glaciers

Ice, in the form of sea ice or land-based glaciers, is capable of storing contaminants deposited by wind. As climate warming causes melting, the ice releases contaminants, either by volatilization or by release of partic-

ulate-associated contaminants into surface water, where further transport or entry into the food chain occurs.

Exposure of Arctic Ocean surface water, as a result of decreasing ice cover, could increase the movement of contaminants such as hexachlorocyclohexanes (HCHs) and toxaphene into the atmosphere, speeding movement within or out of the Arctic (Macdonald et al., 2000a,b).

Sea ice can also transport contaminants by other means, particularly by accumulating contaminants in sediment, from grounding on shallow coastal shelves, particularly where rivers enter the Arctic basin (Barrie et al., 1998). Sediment-rich shallow water can also be incorporated into sea ice by freezing as surface ice is formed. The contaminant-bearing ice can then follow established circulation patterns in the Arctic Ocean, influenced by wind and surface air temperature, releasing contaminant-containing sediment as it melts. While the components of this cycle are well described, climate change could affect any particular step, regionally or throughout the Arctic Ocean, with unpredictable effects on contaminant transport and human health.

Rivers and lakes

River flow into the Arctic Ocean will increase if, as projected by the ACIA-designated climate models, there is an increase in precipitation and the length of the ice-free period for much of the Arctic and subarctic. This will promote increased river transport of contaminants from industrial and agricultural sources further south.

Arctic lakes are thought to have functioned as temporary storage for contaminants deposited in snow during the winter, with rapid runoff removal in spring (Macdonald et al., 2000a). It is possible that an earlier melt, increased contaminant inputs to the lake water, and an earlier onset of spring growth in the lake ecosystem could result in greater amounts of contaminants being incorporated into the ecosystem, and thus into organisms consumed by humans (Macdonald et al., 2002).

Permafrost

Permafrost underlies much of the Arctic. In regions of discontinuous permafrost, contaminants deposited onto the surface by wind, rain, and snow are released during thawing and mobilized into active biological systems or into runoff, eventually draining into lakes, rivers, and the ocean. Permafrost also acts as a containment mechanism for man-made waste sites, such as landfills, sewage lagoons, mine tailings, and dumpsites. Increasing season length and surface air temperatures could allow contaminants to migrate through active permafrost layers to surface water sources used by humans and wildlife. Entry into runoff during periods of increased rainfall is also a possibility. The overall effect of permafrost thawing is likely to be increased contaminant exposure by a variety of mechanisms, and represents a "new" transport pathway.

Wildlife

Pacific salmon (*Oncorhynchus* spp.) spawn and die in freshwater streams and lakes. Contaminants accumulated by a salmon during that part of its lifecycle spent in the North Pacific are deposited into the local freshwater ecosystem where it dies. Over the past decades, as warming has occurred, Pacific salmon species have gradually extended their range north into the Arctic, adding contaminant loads to the predators and local biomass where they spawn and die (Babaluk et al., 2000). The magnitude of this input, for some freshwater systems, has been shown to exceed the input from atmospheric pathways (Ewald et al., 1998). Some contaminants, which are present at higher concentrations in the North Pacific than the Arctic, notably β-HCH, could thus increase in local arctic freshwater systems to levels higher than at present, so increasing the potential for human exposure and possible health effects.

Humans

Potentially, the greatest impact from human activities is from increased maritime traffic during ice-free periods with the sudden catastrophic release of hazardous materials into the local, regional, and eventually circumpolar environment. The possible increase in extreme weather events could increase the likelihood of such an event.

15.4.4.3. Summary

The transport mechanisms and pathways for contaminants in the Arctic are incompletely understood. Time trends are not available for the concentrations of most contaminants in most media, and instrumental records for major forcing factors are equally sparse. Models that link contaminant movement to climate events do not yet exist. All components of all contaminant pathways are affected by climate. The degree of uncertainty in the climate processes precludes prediction based on current climate models, but makes a powerful case for further research, as well as environmental, wildlife, and human health monitoring.

Monitoring and research on contaminant health effects in arctic residents and ecosystems is ongoing, and must now be linked to systematic research on contaminant movements into, and out of the Arctic. A warming climate in the Arctic could offer a variety of new economic opportunities to arctic residents, including increased maritime activity. International efforts should continue at preventing massive contaminant spills in the Arctic: such spills could be the most damaging contaminant event for local and regional ecosystems and residents.

15.5. Environmental change and social, cultural, and mental health

The potential impacts resulting from direct (section 15.3) and indirect (section 15.4) mechanisms of climate change on human health have been presented in previous sections

of this chapter. This section addresses climate change and its link with social, cultural, and mental health.

The association between health and social, cultural, and economic factors has been reported extensively. A gradient has been consistently demonstrated across different socio-economic classes, regardless of how they are defined, for various measures of mortality and morbidity, both for individual diseases and for all causes combined (Marmot and Wilkinson, 1999). This gradient exists in many countries around the world, and has persisted despite major improvements in the overall health and wealth of populations. Also, numerous studies have shown correlations between unemployment and morbidity and mortality (e.g., Morris et al., 1994; Moser et al., 1984). The disparity in health status between Inuit and the larger national populations to which they belong (Canada, Denmark, Russia, United States) has often been attributed to their relatively poorer socio-economic status. Furthermore, the link between socio-economic conditions and health has been demonstrated within arctic populations. In a study of 49 Inuit and Dene communities in the Northwest Territories, based on community-level data from the 1992 NWT Housing Survey and routinely reported health and social service agency data, Young and Mollins (1996) found a correlation between most indicators for housing and socio-economic status with the rate of health center visits, used as a proxy measurement of morbidity. Among Canadian Inuit the proportion of respondents reporting excellent/very good health increased with the level of formal education (Bjerregaard and Young, 1998; Statistics Canada, 1991). Those in the highest income category are also more likely to report excellent health than those in lower income categories. The association between education and positive self-reported health was also found in the 1993-94 Greenland Health Interview Survey (controlled for age and sex) (Bjerregaard and Young, 1998). Among those with the most formal schooling, self-rated health was better in all age groups and with fewer reported longstanding illnesses.

Figure 15.19 represents one view of the interrelationship between health and social, cultural, and environmental factors. At the center of the model is the individual with his or her genetic endowment, physiological adaptation, and personal life experience. Everyday life, for example, work and lifestyle, determine the extent to which individuals are exposed to factors within their immediate surroundings that directly affect health. Such factors include tobacco, alcohol, diet, contaminants, microorganisms, and psychological factors. Everyday life is in turn determined by social, economic, and cultural factors within the wider society. All the individual, social, cultural, and socio-economic factors are influenced by the environment within which they are embedded and by possible changes in this environment (e.g., see Box 15.1).

The effect of change on communities resulting from climate related impacts, for example, by flooding and ero-
Fig. 15.19. Interrelationship between social, cultural, and environmental factors known to affect health.

sion, or warming temperatures and shifts in local resource access and availability, and the links between these changes in the physical environment and individual health are clear. Research using an ecological approach has also shown that the social environment of the community affects population health (Macintyre and Ellaway, 2000). Studies have focused on the extent to which social relations, social capital, and the social vitality of communities influence individual health status (Berkman, 1995; Kawachi et al., 1997; Veenstra, 2002). Although the relationship between the social environment of the community and the health of the individuals is still not clear, studies have shown associations between, for example, social isolation and mortality (Berkman and Syme, 1979) and social capital and poor self-rated health (Kawachi et al., 1999). In both cases the association was present even after adjusting for individual risk factors. Even though the health advantages are not fully understood, research has shown that a healthy community can be characterized as a safe environment that provides opportunities for social integration, and is neither conflictual, abusive, nor violent (Taylor J. et al., 1994).

Research and practice in health promotion have focused on the community level rather than on disease prevention in individuals. The role of the social environment for individual health argues this inclusion. Also, it is widely believed that the positive effects of health interventions result from a high degree of community ownership and participation in defining objectives, planning, and implementation of the initiative (Bracht, 1999; Green and Kreuter, 1999).

Research on health promotion and community health shows that community members' involvement in the social life and their shared pursuit of broader social goals

through psychosocial processes can positively affect health, and that participation is a condition for positive outcome of health promotion efforts.

The potential for future health promotion in combining these two perspectives on community health is obvious as increasing communities' capacity to address problems and to work together to solve them will strengthen the effect of health promotion projects and help to improve the health of the population. Arctic communities have recently undergone rapid socio-cultural change and these changes will be further accentuated by the projected climate changes addressed in Chapter 4. Building communities' capacity to meet these changes is an area that needs further attention throughout the Arctic.

15.5.5.1. Acculturative stress and mental health

The concept of *acculturation* describes the cultural and psychological changes that result from continuous contact between people belonging to different cultural or ethnic groups (Berry et al., 1986; Redfield et al., 1936). At the population level, changes in social structure, economic base, and political organization frequently occur as a result of this contact, whereas at the individual level the changes are in such areas as behavior, identity, values, and attitudes. Berry et al. (1986) described this process in indigenous cultures in relation to the impact of modernization on indigenous people and traditional groups (Fig. 15.20). Climate change can also impact on the traditional way of living via influences on reindeer herding, fishing, and hunting. Alterations of the physical environment can lead to a rapid and a long-term cultural change and loss of traditional culture which can, in turn, create psychological distress and mental health challenges (see Box 15.7).

Group strategies for dealing with changes in ways of living can vary from readily and easily adapting to the changes, to resisting them, or to collapsing under their weight (Berry, 1985). Individuals adopt different acculturation strategies and their mental health is expected to vary both as a function of the strategy itself and in relation to the balance between the strategy which is possible or preferred by the individual and that of the majority group (see Fig. 15.20). From the mental health perspective, integration seems the most successful strategy and marginalization the most problematic, with separation and assimilation being intermediate in relation to mental health (Berry, 1990a; Berry and Sam,

Fig. 15.20. Four modes of acculturation (Berry, 1990b).

Box 15.7. Climate, reindeer herding, and Saami culture

The Saami are indigenous reindeer herding people originally inhabiting arctic regions of Norway, Sweden, Finland, and western Russia. The Saami live in communities which have undergone rapid modernization and cultural revitalization. Some communities are more traditional while others are more modern with regard to the average lifestyle of their residents. In terms of mental health and social well-being, Saami people living in areas strong in culture and traditional ways of life appear just as healthy as the average population in these regions.

However, climate changes could have significant impacts on Saami communities and culture. Increasing temperatures may influence the seasonal migration of reindeer (see Chapters 11 and 12). The consequences of the climate changes are likely to be varied and include causing reindeer to stay for extended periods on less productive fields. Throughout the 1990s, overuse of the pasture lands by reindeer contributed to a crisis within the reindeer herding industry leading to a forced reduction in numbers of reindeer. This in turn forced several reindeer herders to stop herding. According to social workers in the Saami highlands, this led to higher rates of unemployment and dependence on social welfare in these communities. As reindeer herding is seen as a Saami activity, and reindeer herders as the carrier of the Saami culture, those individuals who left herding lost not just an important occupation but also status as an important protector of the Saami culture. Exclusion from this group has been a considerable stress for families and has had significant and far reaching impacts on the Saami culture as a whole.

1997). Marginalization reflects alienation and anomie and is a risk factor for mental health (Berry and Kim, 1988). In integration, relationships to both cultures may provide the strongest socio-cultural foundation for good mental health including bicultural competence and coping strategies necessary for adaptation to both cultures (Berry and Kim, 1988).

The concept of *acculturative stress* refers to stress in which the stressors are identified as being rooted in the process of cultural change or acculturation. For arctic peoples these stressors can be loss of traditional food resources and habitats, unemployment, loss of cultural practices, and migration. Climate change can be an external factor that indirectly initiates the acculturation process by forcing people to behave in new ways, to change their ways of living, and to replace or drop old traditions (see Box 15.7).

Acculturative stress may be associated with psychological changes such as psychosomatic symptoms, feelings of alienation and marginality, and identity confusion (Berry, 1997). If the acculturation experience overwhelms the individual with a feeling of loss of control, psychopathology may occur such as depression and anxiety, substance abuse, and suicide (Fig. 15.21). For instance, if climate change leads to a loss of herding, hunting, or fishing opportunities for people who are closely connected to and dependent upon such activities, this can result in feelings of loss and grief. This might result in longer-term feelings of marginalization which can contribute to substance abuse, depression, and suicide. A study of Saami males living in remote areas found a close relationship between marginalization and depression/anxiety (Kvernmo and Heyerdahl, 2003), while a study conducted in Greenland found that growing up in a town and being fully bilingual, as compared to growing up in a small village and speaking only Greenlandic, was associated with better mental health status (Bjerregaard and Curtis, 2002). This disagrees with the assumptions previ-

ously held that the social and psychological outcomes of acculturation are inevitably negative (Berry and Kim, 1988; Malzberg and Lee, 1956). It appears that successful integration depends on having and taking advantage of the opportunities necessary to meet changing conditions.

15.5.5.2. Examples of the influence of rapid change on psychosocial health

Several examples are used here to illustrate the relationship between the rapid socio-cultural and economic change witnessed in the Arctic over the past 20 to 50 years and the psychosocial health of the populations living there. A good understanding of such links is important in relation to the climate changes projected for the Arctic over the next hundred years (see Chapter 4). Further changes may result from climate-related changes in economic opportunities, traditional lifestyles, and subsistence activities.

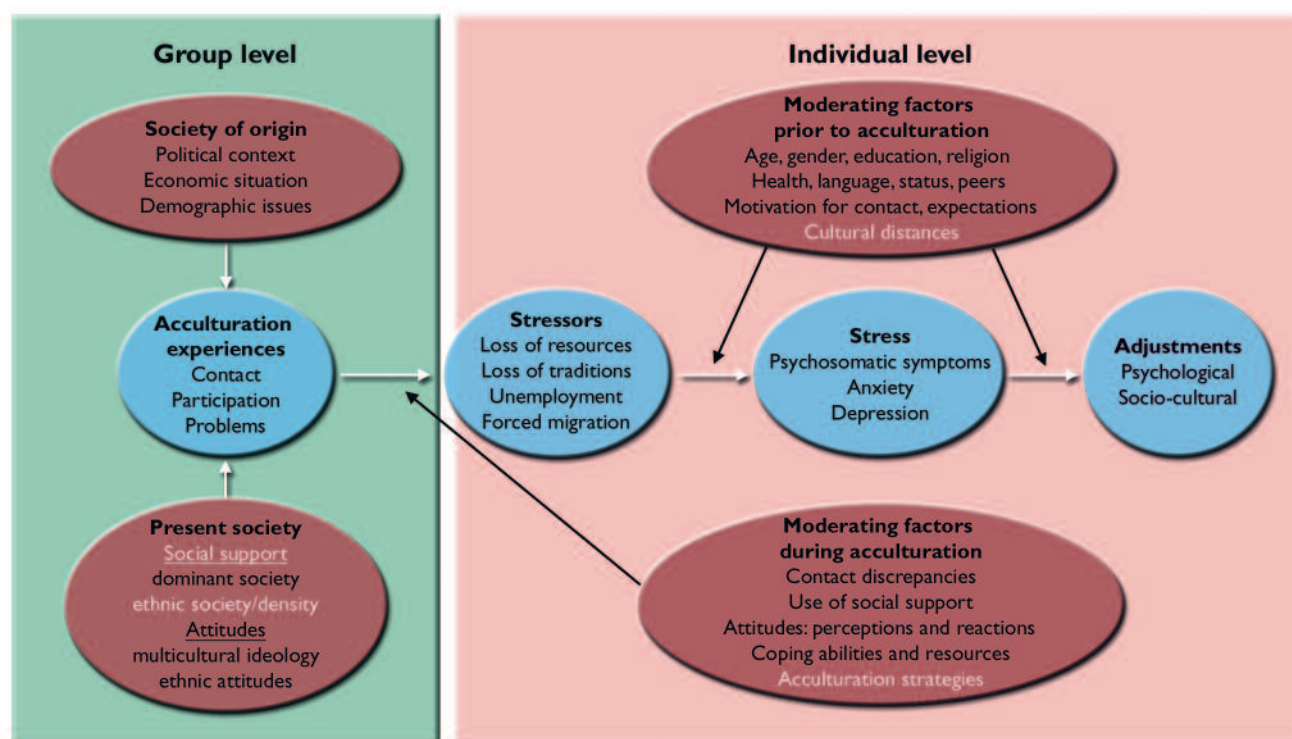
A change in occupational patterns from hunting and small-scale fishing to an increase in wage-earning employment is seen across the Arctic. In Greenland villages, wage earning has been introduced along with institutions and service deliveries such as schools, stores, and sanitation infrastructure. In towns, there are factories and enterprises, banks, shops, and administrative services. The changes in occupational patterns are associated with decreased physical activity and a change from a traditional marine diet to a more western diet in many coastal indigenous groups and this is of particular importance in relation to cardiovascular diseases (Bjerregaard and Young, 1998). In many studies, cardiovascular risk increases with modernization and urbanization, but although mortality from ischemic heart disease is slightly lower among Inuit than in the general population of Denmark, Canada, and the United States, it has decreased over recent years while marine food has been increasingly replaced by store bought food. In contrast, mortality from other heart


Fig. 15.21. Acculturation stress and moderating factors (based on Sam and Berry, 1995).

diseases and stroke is considerably higher in Inuit and shows an uncertain time trend (Bjerregaard et al., 2003). Type 2 diabetes increased considerably over the last 40 years among the Inuit in parallel with processes of modernization (Ebbesson et al., 1998; Murphy et al., 1992). In Greenland, type 2 diabetes is now more prevalent than in Denmark (9.8 and 7.9% in the 40 to 64 year old age range, respectively; Bjerregaard et al., 2003), which leads to speculation about increased genetic sensitivity to environmental pressure in the Inuit. The change in dietary patterns from traditional foods to a more western diet with a higher consumption of store bought foods is important in relation to both the connection with obesity and other cardio-vascular risk factors and with the loss of the socio-cultural values related to eating and sharing traditional foods and their significance for health.

The amount of traditional food and the specific species consumed vary considerably among regions and population groups (Bjerregaard and Young, 1998; Blanchet et al., 2000; Kuhnlein et al., 2000). Older people and people in villages who fish and hunt themselves eat more traditional food, whereas the young wage earners consume more store bought foods often related to their convenience. However, regardless of the levels of consumption, traditional foods are highly valued by all population groups. They are considered filling and healthy and to provide strength, warmth, and energy in ways that store bought food does not (S. Bernier, Public Health Research Unit, Université Laval, Canada, pers. comm., 2002; Borré, 1994; Furgal et al., 2001). Traditional food is also reported to be a significant contributor to cultural identity, tradition, and social cohesion in Inuit communities. To eat and like tradi-

tional food is perceived as a marker of identity in the same way as is speaking the Inuit language (Kleivan, 1996; Searles, 2002).

> *Inuit food has sustained us, nourished us, brought us together, and given us a sense of who we are.*
> Egede 1995

> *... in order to have a Greenlandic identity the person must eat ... and like dried fish, raw mattak, etc.*
> Petersen 1985

> *I can't do without kalaalimernit [traditional Greenlandic food]. I eat it a lot. I was brought up with people who eat kalaalimernit. It tastes good and it feels good for you. For instance when I do sports I feel kind of stronger when I have eaten kalaalimernit.*
> Focus group study: Ilulissat, wage earners

The rapid changes that have taken place within arctic communities and the migration from villages to larger towns has lead to psychosocial stress among populations that within little more than one generation have had to adapt to significantly different ways of life. Those who move may experience a lack of social relations in towns, where still more people live in single-family households and social relations are chosen and individualized. Traditional values may appear irrelevant, as language skills and formal education become the means to succeed and avoid unemployment. However, traditional knowledge and expertise in traditional activities is still very relevant, if not increasingly so, when aspects of the environment become more unpredictable or "risky" in which to practice subsistence activities and travel on land or sea.

Psychosocial stress is reflected in the incidence of social problems seen in many arctic communities today. Whereas alcohol abuse in western societies is usually characterized by an increasing daily consumption over many years, it is the occasional, sometimes regular, drinking spree or binge drinking which creates many problems in arctic communities (Bjerregaard and Young, 1998). The most important health implications are accidents and violence resulting in intentional and non-intentional traumas (cuts, bruises, fractures, head injuries). Drowning, falls, frostbite, burns, and pneumonia also result from intoxication and a direct association between alcohol use and incidence of suicides has been shown. Alcohol consumption is also associated with economic problems and job loss due to instability at work and to domestic abuse.

Studies have shown a high occurrence of violence and sexual abuse in some arctic populations (Bjerregaard and Young, 1998). A survey in Greenland showed that women and men have equally often been victims of violence (47% for women and 48% for men) but that women had more often been sexually abused (25% and 6%, respectively) (Curtis et al., 2002). Having been the victim of violence or sexual abuse was significantly associated with a number of health problems: chronic disease, recent illness, poor self-rated health, and mental health problems. The association between having been the victim of violence or sexual abuse and current health status was stronger for women than for men (Curtis et al., 2002).

Similarly, suicide has played a significant role in many arctic communities and individuals' lives. It has been argued, based on the much higher suicide rate in men than women that women in the Arctic have been more successful than men in adapting to social change. While women have been able to continue their traditional roles as caregivers, both in the family and in the labor market, the transition from hunter and sole bread-winner to wage-earner in a subordinate position or even unemployment has been a difficult transition for many arctic males. On the other hand, studies have shown that women more often than men have suicidal

thoughts and mental health problems (Bjerregaard and Curtis, 2002). The finding that men suffer more from socio-cultural change related stress than women may be in part based on the more visible and more commonly reported manifestations of this stress or frustration common among men (i.e., they are more likely to become violent or to commit suicide). A population survey of adults in Greenland showed significant associations between suicidal thoughts and a number of social and cultural factors, the most important determinants being the occurrence of alcohol problems in the parental home and the experience of sexual violence during childhood (Bjerregaard, 2001). Among Greenlanders who had neither experienced alcohol problems nor sexual violence in childhood, 10% reported suicidal thoughts, while for those who had experienced both, 82% reported suicidal thoughts (Table 15.1).

Alteration in subsistence species, changes in habitability of buildings, erosion of village sites (see Box 15.6), and disappearance of commercially critical species (see Box 15.1) may all cause dislocation of residents from smaller to larger communities, with a subsequent overload of scant resources in the receiving community. This combination of factors and interaction with the capacity of individuals and communities to adapt to or change with these climate and environmentally influenced shifts may have a significant bearing on the social, cultural, and mental health of individuals in arctic communities (for a discussion of community capacity and resilience see Chapter 17).

15.5.5.3. Example scenario of interactions between climate warming, ocean temperature, and health

Climate change can influence health in the Arctic in many ways. These fall into two groups: direct (section 15.3) and indirect (section 15.4) influences. Two indirect pathways are of significance to individual and community health issues related to socio-cultural and economic transition. The first results in reduced opportunities for subsistence hunting and fishing as a result of changes in animal or plant populations, an increase in extreme events, and changes in sea-ice distribution and thickness, while the second forces populations to move. These factors include the movement or loss of crucial species for subsistence hunting, coastal erosion, breakdown of sanitation infrastructure, and increasing difficulties in maintaining transportation systems for goods and people. Both pathways, of which the latter is also a consequence of the former, may be related to climate changes and may be seen as mediated through acculturation and cultural loss. However, the modernization process in arctic communities over the last 50 years has been accompanied by a growth in the cash economy, making it increasingly difficult to maintain a livelihood from hunting and fishing and therefore encouraging people to move to more regional economic centers.

Table 15.1. Prevalence of serious suicidal thoughts in Greenland Inuit according to childhood experience of alcohol misuse and sexual violence (Curtis et al., 2002).

	No sexual violence during childhood (n=1150)	Sexual violence experienced during childhood (n=65)
	%	%
No alcohol problems in parental home (N=760)	10.3	21.7
Occasional alcohol problems in parental home (N=355)	18.2	48
Often alcohol problems in parental home (N=100)	39.8	82.4

Figure 15.22 shows two possible pathways between a cooling of ocean temperatures and decreased health status in indigenous communities. The first is via a reduction in the catch of commercially important species. This happened in Greenland in the 1960s when Atlantic cod disappeared from coastal waters off West Greenland (see Box 15.1). Unless new sources of income are generated, reduced catches will result in deterioration in economic conditions and unemployment. Unemployment is associated with social and mental health problems in communities, increased use of alcohol and violence, and suicide.

The second pathway of impacts is via a change in the availability of subsistence species. Historically, indigenous groups have responded to such a change by moving with the animals to places with better catches, however, human migrations are now far less easy with today's settled villages. Decreased opportunities for catching seals, for example, result in both dietary changes and a loss of the knowledge required to recognize, harvest, and prepare traditional foods (Kuhnlein and Receveur, 1996), and in a sense of cultural loss as hunting and food sharing is important for the identity and maintenance of the social well-being of the community (Borré, 1994). The lack of subsistence species also drives an eventual migration of individuals to towns where some will face unemployment. The shift from a traditional marine diet to a more western diet, along with other behavioral changes that follow the transition from a lifestyle based on hunt-

Fig. 15.22. Example scenario of the link between climate-related changes, and community and individual health in indigenous communities in Greenland.

ing and fishing to a more sedentary wage-based economy lifestyle, is of major importance in relation to the occurrence of cardiovascular disease in Inuit populations.

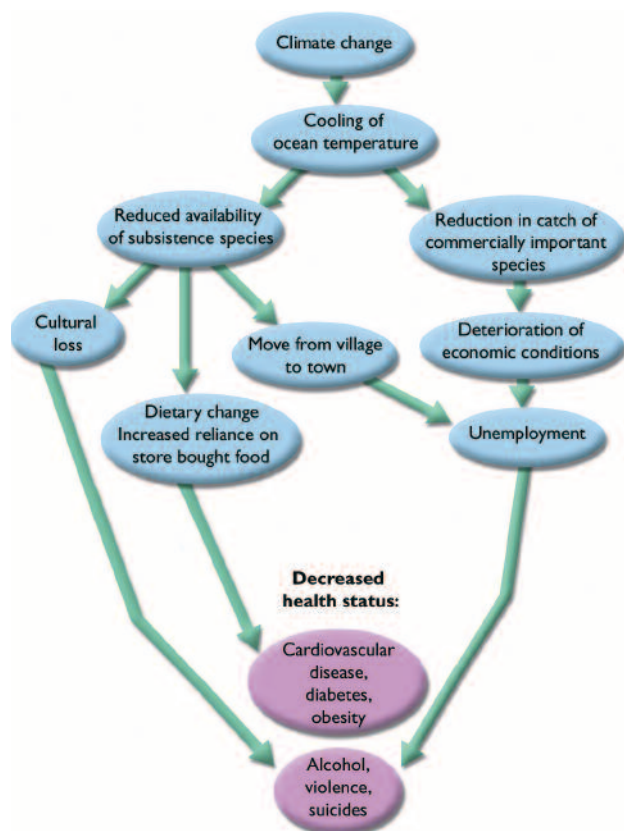
In spite of of the present cooling trend in parts of Greenland, the climate scenarios described in Chapter 4 project a warming trend for Greenland over the next 100 years. The health impacts of this warming are likely to be mediated by the same indirect mechanisms discussed in section 15.4. Changes in the distribution of commercially important fish species, as well as in subsistence species could affect health in the same way as ocean cooling. Increased risk to hunters and travelers due to ice changes, and political and economic policy decisions which result in the relocation of populations are also likely to have major health impacts.

It is unlikely that periodic warmer weather could result in the same detectable changes in mortality from cardiovascular disease and stroke that are seen in large populations in the northern temperate zones of Europe and North America. The scattered, sparse population of the present cooling region of Greenland is too small for a significant number of well-documented mortality events.

Significant warming in Alaska since the 1970s has resulted in significant impacts. Permafrost thawing and lack of sea-ice protection have resulted in the imminent threat of forced village dislocation, with severe stress on families. River and coastal erosion with continued warming will make this more widespread. In addition, the northward spread of beaver populations has resulted in the obstruction of many streams traditionally used by villages for surface water supply. Contamination of these sources by the zoonotic parasite *Giardia lamblia* makes outbreaks of human disease much more likely. At the same time, moose have extended their range into new regions and waterfowl habitat is increasing, making new subsistence foods available. Thus, in Alaska, new risks and new opportunities have resulted from warming. This makes the development of community monitoring a more urgent task, as only data will enable policy and public health responses to mitigate risks and maximize opportunity.

Despite the arguments made here for the connections between environmental change, socio-cultural transition, and health in the Arctic, many negative health outcomes are attributable to causes other than climate change. The modernization process in indigenous communities in the Arctic since the 1950s has been accompanied by many such health outcomes (e.g., increased use of alcohol, more violence, and higher mortality from suicides, heart disease, and diabetes), without any yet-reported association with climate change.

15.5.5.4. Summary

Health is a multifactorial concept, influenced by a variety of determinants, climate change being one of many environmental factors. Many of these determinants are still poorly understood. The rapid social, cultural, and


economic transition that arctic communities have seen over the past 50 years has influenced lifestyles and individual and community health. These changes are very likely to be affected and even accentuated by climate change in the future. The influence of adaptive behaviors resulting in changes to lifestyle and cultural loss further influence acculturative stress in arctic communities. Climate change has the potential to influence the rapid changes ongoing in communities today by challenging individuals' and community's relationship with their local environment, which has for thousands of years, been the basis of their identity, culture, and well-being.

15.6. Developing a community response to climate change and health

Health impacts related to climate change in the Arctic are likely to vary across communities and regions, with some changes being positive and others adversely affecting the health of individuals. In response to these impacts, communities need to develop strategies to take advantage of opportunities and to minimize risks. In some cases, communities have already started to adapt to climate related changes with potential impact on aspects of health. For example, in Inuit communities of the western Canadian Arctic, individuals report now taking bottled water on trips due to the lack of fresh water sources while on the land and hunters have adapted their hunting and fishing times to compensate for the changes in species availability and access to continue to procure fresh traditional foods (Nickels et al., 2002). A key component in this ability to adapt and respond is the development of a better understanding of the relationship between climate and the health of northern peoples and access to locally relevant information on the changes taking place. The identification, selection, and monitoring of some basic indicators for climate and health is one tool communities can use to help in the development of their response to these changes. This information can support the community's capacity to know what changes are occurring, what changes are likely to take place in the future, and what impacts these changes may have. Linking these indicators to the projected scenarios of change reported in other chapters of this assessment allow communities to monitor, and where required develop strategies to minimize negative impacts in the future. This section proposes some candidate indicators for this purpose based on the scientific review of direct and indirect climate–human health interactions presented in this chapter.

15.6.1. Goals of community indicators

The identification, selection, and monitoring of indicators is one way in which communities can gather the information to support their diagnostic needs and to support the development of potential response strategies. Within this context, indicators for climate change impacts on human health are measurements or observations of a parameter (e.g., snow, ice, water, temperature, UV-B radiation, permafrost, a component of human health) that link climate, the environment, and an aspect of community or

individual health. The indicators selected by the community need to be issue-specific and must be presented in a way that makes the information they generate easy to understand and useful in making decisions about climate change and health impacts at the community level.

Indicators can potentially serve many purposes. For example:

- To confirm changes or trends in a condition over time (e.g., date of freeze-up of the local bay).
- To assess the current condition of the environment to judge its adequacy with reference to a standard (e.g., safety of ice for travel).
- To anticipate hazardous conditions before negative impacts occur (e.g., to know when a severe storm event is coming or to predict a shortage of a fresh source of a specific traditional food in the community related to difficulties with access and availability).
- To identify causes of effects and to identify appropriate action (e.g., windchill factor to warn people about cold injury).

The type(s) of indicators chosen by a community or region for a monitoring program must be determined by the specific goals of the community. For example, whether it is the intent to be able to warn individuals of future dangerous conditions, whether it is to determine if an increase in accidents experienced by residents while on the land or water is associated with changes in local climate conditions, or whether it is to determine if changes in local food security (access and availability of traditional food species) are associated with changes in climate and whether this situation will become sufficiently bad in the future that they must be prepared to take early action. In many cases, regional and community public health and other authorities (e.g., Meteorological Service/Weather Bureau, Wildlife Dept.) can be helpful in selecting and gathering such indicator-based data. A good definition of goals for the monitoring activity will provide direction as to what indicators are best suited to their needs and are most appropriate to the community or region. The scale at which the indicators are gathered is also critical as some changes can be detected and are best managed at a regional scale (e.g. changes in access to market foods to supplement local diets at critical times of the year) while others require a more local-scale approach (e.g., monitoring permafrost stability at the airstrip of a community). In all cases, for indicators to be appropriate, meaningful, and useful to local communities, community individuals must be directly involved in their identification and selection as well as in the design and implementation of the data gathering monitoring programs (Eyles and Furgal, 2002).

15.6.2. Characteristics of useful indicators

Criteria can be used to guide indicator identification and selection to ensure that appropriate indicators are chosen to help meet community objectives. It is essential that each community or region develops its own crite-

ria, although many may be general and useful to all regions. Two general types of criteria that are often used are scientific and use-based criteria.

Scientific criteria are intrinsic to the issue of scientific quality (sensitivity, reliability, and statistical validity) and are often addressed by using indicators from existing and recognized lists. Indicators based on traditional or indigenous knowledge are very useful and should include a description, where possible, of the understanding of the link between the indicator and the specific health impact. It is also important to consider other "use-based" criteria, such as:

- Feasibility (are they already available and if not, what is the feasibility of collecting new information, taking account of cost, ease and time for collection, capacity to gather data, etc.).
- Perceived importance of the indicator to those affected (community representatives).
- Number of indicators (a manageable number is needed to attain specified goals, but this number must not be too cumbersome for community monitoring system managers).
- Balance (a rough balance among the various aspects of the issue).
- Catalyst for action (those that act as a catalyst to drive action are also useful, e.g., ice thickness on travel routes).
- Understandability by the media, local decision-makers, and policy-makers.
- Minimal environmental impact to collect.
- Relevance to all members of the population.

The candidate indicators listed in the following section are proposed on the basis of the review presented in this chapter and all meet the following basic criteria:

- The indicator relates climate changes, directly or indirectly, to potential human health impacts.
- The data are already being gathered by regional or national governments or are readily available from other sources.
- Where the indicator data are not already gathered, they could be easily collected by communities using standard methods.
- Time trend data for the indicator exist or can be easily gathered.

15.6.3. Proposed candidate indicators

This section lists indicators proposed as potential candidates for community selection. They are not an exhaustive or complete list but are proposed as tools to assist communities in discussing and identifying their own indicators. They are derived from the review of direct and indirect climate–human health interactions presented in this chapter and assume the collection of general environmental data related to climate changes at the local and regional scale (e.g., temperature, precipitation, ice cover).

15.6.3.1. Direct impact mechanism indicators

The collection of some basic indicator data can help communities monitor the direct impacts of climate on health in northern communities. Table 15.2 identifies indicators of health impacts related to direct interactions with climate variables such as accidents while on the land or ice (unintentional trauma) related to bad weather conditions, deaths or injuries related to extreme weather events, and the health impacts of increased UV-B exposure.

15.6.3.2. Indirect impact mechanism indicators

Similarly, the monitoring of basic indicators, such as those presented in Table 15.3 can be used to help

Table 15.2. Direct impact mechanism indicators.

Useful health indicators
- General health statistics (see AMAP, 2003)
- Rates of cold injuries (e.g., frostbite)
- Rates of coronary heart disease
- Rates of unintentional injury
- Rates of intentional injury

Extreme weather events, thermal stress, and health
- Extreme event-related use of regional and community rescue services
- Unintentional injury mortality associated with extreme weather events
- Highest and lowest seasonal temperature
- Number of days in winter with extreme low temperature (where extreme is defined as deviation of more than 20% below the average monthly temperature in winter)
- Number of days in summer with extreme high temperature (where extreme is defined as deviation of more than 20% above the monthly average temperature in summer)
- Reports of respiratory trouble (hospitalization)
- Deaths due to exposure in winter

UV-B radiation and health
- Incidence of skin cancers in arctic regions
- UV-B radiation measurement/ozone depletion measurement in arctic regions

Indicators for annual monitoring[a]
- Measurements of UV-B radiation at ground level and at the personal level by integrating or spectral radiometers and personal dosimeters
- Incidence of sunburns especially the time at which increases in sunburn begin to be noted throughout the Arctic
- Number of cases of snow blindness and frequency of reports
- Increases in cold sore occurrences which may indicate suppression of immunity against Herpes simplex virus (Type 1) and other aspects of cell-mediated immunity by UV-B radiation
- Increases in cataract on an annual basis throughout the Arctic

[a] with emphasis on ozone depletion episodes as sunlight increases throughout the arctic spring and summer

Table 15.3. Indirect impact mechanism indicators.

Wildlife populations and health

- Government harvest data by species of interest (key country food species, sentinel species)
- Stock assessments of species of interest and importance to local economies and diet
- Local arrival/departure dates of migratory species
- Frequency of reports of new species to a region
- Important animal disease frequency (e.g., rabies, brucellosis)
- Appearance of new zoonotic diseases (e.g., West Nile virus)
- Local hunter/fisher reports of animal/fish abnormalities
- Registry of reportable infectious diseases spread from animals to humans and through contaminated water
- Incidence of human cases of zoonotic diseases

Ice, snow, and health

- Rates of cold injuries (e.g., frostbite)
- Mortality rates from coronary heart disease
- Rates of unintentional injury

Infrastructure and health

- Movement measurements of structures on permafrost
- Measurements of key shoreline and river bank erosion rates
- Measurement of trends in flood depth and frequency
- Increased repair costs for sanitation infrastructure, boardwalks, and roads
- Increased operational costs for water treatment systems
- Increase in regulatory noncompliance events for sanitation systems
- Increases in pollution of waterways caused by human waste or solid waste leachate
- Increased incidence of waterborne disease outbreaks
- Increased incidence of certain cancers caused by waterborne contaminants
- Increased incidence of diseases associated with poor personal hygiene
- Increased incidence of diseases caused by contact with wastewater contaminants
- Increased reports of damage to sanitation infrastructure caused by erosion, flooding, or foundation failures
- Increased reports of water rationing caused by drought

Society, culture, and health

- Number of in-migrants to regional hub communities per year, and by number of families
- Number of out-migrants from a region's villages, per year
- Incidence of legal encounters for child abuse, assault, and alcohol-related offences
- Community and regional trends in unemployment
- Community and regional rates of completion of 12 years formal education
- Incidences of treatment for depression and post-traumatic stress disorder
- Consumption of traditional food species (frequency, total amount, and percentage composition of total diet)
- Self-reported health status from regional health surveys

communities identify, understand, and track the indirect impacts climate variables may be having on community and individual health in the circumpolar North. Impacts related to exposure to zoonotic diseases, indirect injuries related to environmental conditions, changes in the stability and safety of community infrastructure, and the combined impacts of climate-related changes on social and mental health and well-being can be monitored via the collection of such data.

15.7. Conclusions and recommendations

This chapter discusses direct and indirect relationships and impacts, both positive and negative, between climate-related changes and human health in northern communities. The likelihood of these impacts occurring in any specific community or region is difficult to determine. The risk of impact depends on many factors, both current and future. The most obvious conclusion that can be drawn is that much research remains to be done on the relationship between climate change and individual and community health in the Arctic. Climate will continue to influence public health in the small remote communities of the Arctic. The recent record warming, and the scenario of future warming, combined with the multiple mechanisms by which climate impacts on health indicate urgent need for adopting community-based monitoring strategies. A network of such communities, within and across regions, reporting a common set of similarly measured climate, health status, infrastructure, and ecosystem observations would serve to identify both emerging threats, and opportunities. In addition, this would allow utilization of public health data to quantify impact, and provide the basis for resource advocacy, and to suggest mitigation strategies, as well as jurisdictional policy. Communities must monitor changes that may represent threats or adverse impacts. Where possible, they must proactively develop coping or adaptation strategies. Similarly, they must take advantage of potential opportunities that these environmental changes present. Thus, regional and national governments need to assist in the design, and provide support for community based monitoring and mitigation strategies to cope with climate change.

15.7.1. Principal conclusions and recommendations

1. **There is a lack of comparability in health status data between countries.**

   A core group of health status indicators, gathered and defined identically, should be a high priority for Arctic Council member nations.

2. **There is a need for a carefully planned strategy, at the community and regional level, to monitor and document environmental change.**

   Arctic Council members and program workgroups should provide technical assistance regarding mon-

itoring strategies, climate impact mitigation and pilot studies, data analysis, and evaluation.

3. There is a lack of an organized effort to collect and utilize indigenous knowledge regarding climate and climate changes.

Indigenous knowledge, and its preservation, should be encouraged among Arctic Council member nations.

4. There are few data on the impact of changing UV-B exposure in the Arctic on the biota and human residents. There is little systematic monitoring of ground-level UV-B radiation.

Academic and United Nations organizations have created UV-B research strategies. With regional and community collaboration, research and monitoring strategies relevant to circumpolar populations should be created.

5. There are few data on climate change impacts on regional biota. A critical need exists for the monitoring of wildlife diseases, and human–wildlife disease interaction. There are few data on climate-induced changes in the diet of subsistence species, which affects their nutritional value in traditional diets.

Arctic Council programs have the expertise to design effective regional and international monitoring programs in cooperation with communities. This critical activity should be given a high priority.

6. There is no systematic monitoring in all regions for safety of snow and ice conditions for local/regional travel and subsistence activities.

Regional governments should collaborate with communities to establish appropriate monitoring and communication networks; dissemination of appropriate traditional and modern survival skills should be systematically taught to children and young people.

7. Monitoring is critical in regions of the Arctic where physical infrastructure depends on permafrost or where a village site depends on sea ice protection from storm erosion.

Regional governments should assist in developing community-based monitoring.

8. Data on contaminant transport into and out of the Arctic is critical for projecting impact and risk for arctic wildlife and resi-

dents. Changing climate makes monitoring essential.

International coordinated research and monitoring of changing contaminant transport pathways should continue and expand where needed.

In all areas, there is a need for local and regional integrated analyses of the associations between arctic health status and climate variables. This can be accomplished by the establishment of monitoring and data collection mechanisms where they do not already exist. Also, public health education programs should incorporate, where possible, information on risks associated with the environmental changes most relevant to their region.

15.7.2. Recommendations for monitoring and research

Specific recommendations for monitoring and research are as follows.

Thermal stress and arctic human health

Establish organized monitoring and data collection programs (inclusive of local perspectives and indigenous knowledge) involving, but not limited to, the indicators identified in this chapter to support community understanding of changes in arctic health owing to thermal stress.

UV-B radiation and arctic human health

Measure incident UV-B radiation at ground and individual levels using personal dosimeters and ground-based integrating and spectral radiometers.

Carry out cross-sectional population based surveys and follow-up studies in the Arctic and other areas to investigate the causal relationship between UV-B irradiance and cataract and other UV-B induced health effects to the eye such as climatic droplet keratopathy.

Compile local residents' knowledge and perceptions of UV-B radiation and its effects on health in order to supplement scientific data and obtain new knowledge about existing UV-B related habits, particularly with regard to skin, and immune system and eye impacts.

Establish an international network of UV radiation research centers and monitoring programs.

Expand collection of epidemiological data on key UV-B and health issues (e.g., arctic cataract data are difficult to obtain as are sunburn and cold-sore data).

Wildlife, diet, and health

Establish community based and regional scale monitoring programs for the indicators identified in this chapter.

Where problems are identified (e.g., increasing incidences of exposure to zoonotic diseases), establish surveillance programs to protect the health, social, economic, and cultural benefits of harvesting subsistence species while maintaining confidence in and the benefits of consuming these foods.

Snow, ice, and arctic community health

Establish surveillance and communication networks at the community level to support early warning of dangerous conditions for travel and land-based activities (weather, ice conditions, etc.).

Provide support for community freezers and other food supplement and food safety programs to ensure access to safe and healthy traditional foods in arctic communities.

Develop education programs for young people, based on traditional survival skills, to enhance individual capacity to continue aspects of a traditional lifestyle.

Infrastructure and arctic human health

Establish local level monitoring programs for data collection on permafrost and infrastructure stability.

Monitor ground temperatures and compare to historic measurements.

Monitor basal depth of permafrost and compare to historic measurements.

Monitor coastal and river bank erosion and compare to historic measurements.

Monitor incidence of flooding caused by storm surges or heavy precipitation.

Monitor emergency projects for repair of failing infrastructure.

Society, culture, climate, and arctic health

Research the role of the environment, specifically climate-related variables, in community change for small remote locations.

Research to support the understanding of the cultural context and variables influencing individual and community vulnerability, capacity, and resilience in relation to the impacts these changes represent.

Summary

This chapter discusses the potential impacts of climate change on arctic infrastructure. Particular concerns are associated with permafrost warming and degradation, coastal erosion, the stability and maintenance of transportation routes, and industrial development. Adaptation, mitigation, and monitoring techniques will be necessary to minimize the potentially serious detrimental impacts.

Infrastructure is defined as facilities with permanent foundations or the essential elements of a community. It includes schools; hospitals; various types of buildings and structures; and facilities such as roads, railways, airports, harbors, power stations, and power, water, and sewage lines. Infrastructure forms the basis for regional and national economic growth.

Climate change is likely to have significant impacts on existing arctic infrastructure and on all future development in the region. In most cases, engineering solutions are available to address climate change impacts, thus the issue is more economic than technological. It is possible that the uncertainty associated with projections of future climate change will increase the cost of new projects in the Arctic.

Permafrost engineers must address the problem of preserving infrastructure under projected future climate conditions. One solution is to construct new buildings as existing ones are damaged and abandoned. It is possible that this method will be inadequate, since the required rate of new construction rises exponentially using the climate projections presented in this assessment. In areas of warm, discontinuous permafrost, it is very difficult to find economic solutions to address the impacts of climate change on foundations or structures. These areas, together with the coastal zone where the combined problems of increased wave action, sea-level rise, and thermal erosion have no simple engineering solutions, present the greatest challenges in a changing climate.

Projected increases in temperature, precipitation, and storm magnitude and frequency are very likely to increase the frequency of avalanches and landslides. In some areas, the probability of severe impacts on settlements, roads, and railways from these events is very likely to increase. Structures located on sites prone to slope failure are very likely to be more exposed to slide activity as groundwater amounts and pore water pressures increase.

An increasing probability of slides coupled with increasing traffic and population concentrations is very likely to require expensive mitigation measures to maintain a defined risk level. The best way to address these problems is to incorporate the potential for increasing risk in the planning process for new settlements and transportation routes.

16.1. Introduction

There are increased concerns related to the impact of projected climate change on arctic infrastructure, particularly how future climate change may:

- increase the environmental stresses structures are exposed to, particularly in comparison to design specifications, and cause increased risk and damage to infrastructure and threat to human lives;
- affect geohazards and the impacts of extreme events;
- affect natural resource development scenarios in the Arctic; and
- affect socioeconomic development in the Arctic.

Figure 16.1 presents a flow diagram of the questions that need to be answered in order to complete an impact study. Relevant information from indigenous peoples on infrastructure is given in Chapter 3.

16.2. Physical environment and processes related to infrastructure

Chapter 6 has a detailed presentation of the physical environment and processes in the Arctic related to permafrost (section 6.6), snow cover (section 6.4), precipitation (section 6.2), and sea-ice cover and extent (section 6.3), and can be used as a reference for the discussions presented in this chapter.

16.2.1. Observed changes in air temperature

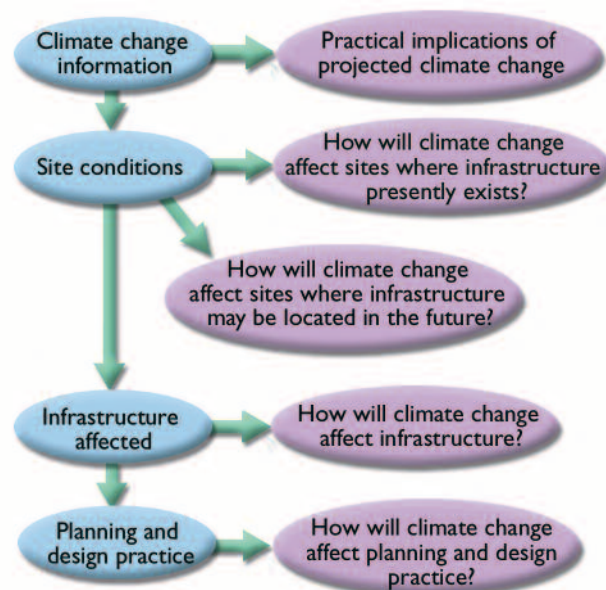
Changes in arctic climate over the past century can be determined by using data from standard climate stations on land and measurements taken on drifting ice floes in the Arctic Ocean. These data show a consistent trend of increasing air temperatures in the Northern Hemisphere during the 20th century, although the


Fig. 16.1. Flow diagram of chapter structure and questions to be answered.

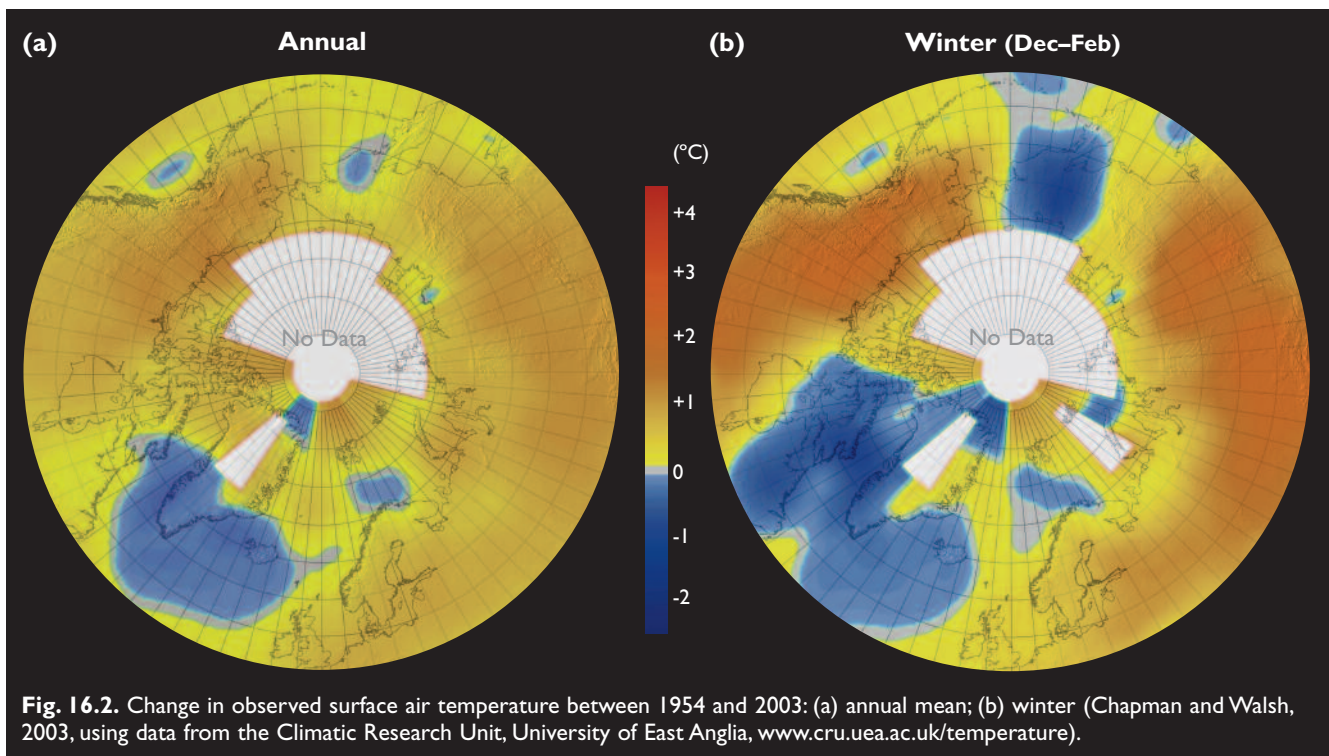
Fig. 16.2. Change in observed surface air temperature between 1954 and 2003: (a) annual mean; (b) winter (Chapman and Walsh, 2003, using data from the Climatic Research Unit, University of East Anglia, www.cru.uea.ac.uk/temperature).


observed changes are not spatially uniform (Anisimov, 2001). While in some regions of the Arctic the warming trend was as great as 5 °C per century, areas of decreasing temperatures were observed in eastern Canada, the North Atlantic, and Greenland (Anisimov and Fitzharris, 2001; Borzenkova, 1999a,b; Jones et al., 1999; Serreze et al., 2000).

Figure 16.2 shows the change in observed surface air temperature between 1954 and 2003 (see also section 2.6.2). Patterns of annual air temperature change indicate that the recent warming has been greatest in Alaska, northwestern Canada, and Siberia (Fig. 16.2a). Temperature increases in winter were much greater than increases in the annual mean temperature: up to 3 to 4 °C over Alaska, northwestern Canada, and Siberia (Fig. 16.2b). In southern Greenland and Iceland, annual mean temperatures decreased by approximately 1 °C, while winter temperatures decreased by 1 to 2 °C. A winter temperature decrease of 1 to 2 °C was also observed in Chukotka.

On the North Slope of Alaska and in northern Siberia, air temperatures increased by 2 to 4 °C, while the global mean air temperature increase over the 20th century was only about 0.6 °C. This pattern is consistent with the hypothesis that the contemporary warming is largely caused by anthropogenic greenhouse gas emissions. Section 2.6.2 discusses observed arctic temperature changes in detail, while section 4.4.2 provides projections of future arctic temperature change.

16.2.2. Permafrost

Permafrost underlies most of the surfaces in the terrestrial Arctic. Permafrost depths vary from a few to

many hundreds of meters (Brown et al., 1997). At selected locations in Yakutia with a cold continental climate, permafrost occurs to depths of 1500 m. Most biogeochemical and hydrological processes in permafrost are confined to the active (seasonally thawed) layer, which varies from several tens of centimeters to several meters in depth. Seasonal thaw depth and the temperature of the frozen ground are two important parameters that must be accounted for in the design of infrastructure built on permafrost. These parameters control key cryogenic processes, such as creep, thaw settlement, adfreeze bond (bond between frozen soil and the material embedded in it), frost heave, and frost jacking (annually repeated foundation uplift caused by frost heave; see Andersland and Ladanyi (1994) for further discussion of these processes). Seasonal thaw depth and frozen-ground temperature both depend on ground-surface temperature, heat flow from the interior of the earth, snow cover, vegetation, and soil properties.

Owing to their low thermal conductivity, snow cover and vegetation (with the underlying organic layer) attenuate annual variations in air temperature and are important regulators of permafrost temperature and depth of seasonal thaw at the local scale. The temperature of permafrost under a thick layer of snow may be several degrees higher than in nearby permafrost that lacks snow cover. In summer, the thermal conductivity of the vegetation and underlying organic layer is typically much smaller than in winter. This reduces summer heat fluxes and keeps permafrost temperatures lower than they would be in the absence of vegetation. A controlled experiment near Fairbanks, Alaska, produced permafrost degradation to a depth of 6.7 m over a 26-year period, simply by removing the insulating

layer of vegetation (Linell, 1973). Finally, thermal conductivity is typically 20 to 35% lower in thawed mineral soils than in frozen mineral soils. Consequently, the mean annual temperature below the level of seasonal thawing may be 0.5 to 1.5 ºC lower than on the ground surface.

The extreme arctic environment requires unique cold-regions engineering and infrastructure solutions that account for severe climate conditions, the presence of permafrost, and various cryogenic processes that may have destructive effects on structures. Since infrastructure is designed to withstand variations in environmental parameters within a prescribed range, information about past changes in arctic climate and environmental conditions is crucial for developing optimum engineering solutions for future infrastructure and safe management of existing structures.

16.2.2.1. Observed changes in permafrost

Changes in permafrost temperature due to increasing air temperatures were observed in Russia as early as 1970. Pavlov (1997) presented data indicating that the mean annual permafrost temperature increased by 2.0 to 2.5 ºC at a depth of 3 m and by 1.0 ºC at a depth of 10 m between 1979 and 1995. Observations of soil temperature changes at the Marre-Sale geocryological station in the southwestern region of the Yamal Peninsula (Table 16.1) are especially illustrative. Similar changes have been observed in Alaska (Osterkamp and Romanovsky,

1999) and elsewhere (section 6.6.1.2). Changes in active-layer thickness have also been observed.

The Global Terrestrial Network for Permafrost (GTN-P) and the Circumpolar Active Layer Monitoring (CALM) program were established to monitor such changes. The GTN-P was initiated by the International Permafrost Association (IPA) to organize and manage a global network of permafrost observatories for detecting, monitoring, and projecting climate change (Burgess et al., 2000b). The network, authorized under the Global Climate Observing System and its associated organizations, consists of two observational components: the active layer and the thermal state of the underlying permafrost. CALM, established in 1990, provides the active-layer monitoring component (Brown et al., 2000), while GTN-P provides monitoring of the thermal state of the permafrost. The European Community project, Permafrost and Climate in Europe, contributes to the GTN-P and monitors nine boreholes in mountain permafrost (see also IPCC, 2001).

16.2.2.2. Observed changes in freezing and thawing indices

The strength and deformation characteristics of frozen soils are dependent on soil type, temperature, density, ice content, unfrozen water content, salinity, stress state, and strain rate (section 16.2.2.5). Thawing of frozen soil, or even an increase in the temperature of frozen soil, may lead to deteriorating strength and deformation characteristics, accelerated settlement, and possible foundation failure.

The design of foundations in permafrost regions must, therefore, always include an evaluation of the maximum active-layer thickness and permafrost temperature that may occur in the foundation soils during the lifetime of the structure. The initial and long-term bearing capacity of the foundation can then be determined.

Table 16.1. Soil temperatures measured between 1979 and 1995 at the Marre-Sale station, southwestern Yamal Peninsula, Russia (Pavlov, 1997).

Description of ground surface and subsurface soil type	Depth (m)	Soil temperature (°C) Mean	Soil temperature (°C) Increase
Slope with willow–green moss cover; sand to 0.7 m, loam	3	-5.4	2.2
	6	-5.3	1.2
	10	-5.2	0.8
Horizontal hilly peatland with grass–shrub–moss–lichen cover; peat to 0.75 m, ice, sand	3	-5.6	1.1
	6	-5.6	1.0
	10	-5.6	0.7
Polygonal tundra with moss–lichen–grass–shrub cover; sand	3	-6.5	1.3
	6	-6.5	1.1
	10	-6.4	0.6
Runoff zone on gentle southern slope, cloudberry–sedge–sphagnum–hypnum bog; sand, loam	3	-3.6	0.5
	6	-3.8	0.2
	10	-3.9	0.1
Bottom of dried lakes, meadow bottom with sedge–hypnum bog; peat-enriched sand	3	-3.4	1.1
	6	-3.8	0.7
	10	-3.9	0.5
Hilly and tussocky polygonal tundra covered with shrub, grass, and lichen; sand	3	-4.2	1.2
	6	-4.4	1.0
	10	-4.4	0.7

Table 16.2. Number of meteorological stations in each ACIA region (Instanes and Mjureke, 2002a).

	ACIA region	Number of stations
Iceland	1	1
Svalbard	1	1
Norway and Finland	1	2
Northwest Russia	1	1
Siberia	2	6
Alaska	3	5
Canada	4	3
Greenland	4	2

Region 1: Arctic Europe, East Greenland, European Russian North, North Atlantic
Region 2: Central Siberia
Region 3: Chukotka, Bering Sea, Alaska, western arctic Canada
Region 4: Northeast Canada, Labrador Sea, Davis Strait, West Greenland

Instanes A. (2003) presented a review of the use of air freezing and thawing indices for permafrost engineering design. The air thawing index (ATI) is a useful parameter to determine the "magnitude" of the thawing season and can be used to calculate active-layer thickness and maximum permafrost temperatures. The air thawing index is defined as the integral of the sinusoidal variation in mean daily or monthly air temperature (T) during one year for T >0 °C (the air freezing index, AFI, is defined as the integral of the sinusoidal air temperature variation during one year for T <0 °C).

Ground-surface temperatures differ from air temperatures. If observations of ground-surface temperatures are not available, they can be estimated from air temperatures using an empirically determined n-factor. Andersland and Ladanyi (1994) listed approximate n-factors for different types of surfaces. Variations in snow cover will also affect ground temperatures.

Instanes A. and Mjureke (2002a) carried out an extensive analysis of historic freezing and thawing indices for arctic meteorological stations. Many of these stations have more than 100 years of continuous temperature records. The data used in this analysis were mean monthly air temperatures from Russian datasets provided by O. Anisimov (State Hydrological Institute, St. Petersburg, Russia, 2001).

Twenty-one stations were chosen for this study, using the following criteria:

- the four ACIA regions (section 18.3) should be represented;
- station time series should be of considerable length (>30 years);
- station time series should be continuous;
- priority should be given to meteorological stations located near population concentrations and major infrastructure; and
- stations should be evenly distributed throughout the Arctic.

All the stations are north of 60° N and within the area covered by the Arctic Monitoring and Assessment Programme (AMAP) and the ACIA. Table 16.2 shows the number of stations in each ACIA region.

From an engineering point of view, current and past design levels of thawing and freezing indices are of interest mainly in comparison with values projected for the future. The impact of climate change on arctic

[a]percentage of years with an air thawing index higher than the mean for the entire period of record plus one standard deviation; [b]the value from an ideal random data series, without trends; [c] + indicates warming, (+) indicates weak or possible warming, 0 indicates no trend, (-) indicates possible or weak cooling, and - indicates cooling; [d]percentage of years with an air freezing index lower than the mean for the entire period of record minus one standard deviation.

infrastructure will be very dependent on how future temperature levels relate to past design levels and historic variability at a specific site. However, an analysis of historic records in terms of freezing and thawing indices can provide indications of temperature increases between 1981 and 2000 (Instanes A. and Mjureke, 2002a).

Table 16.3 presents the percentage of unusually warm summers and unusually warm winters between 1981 and 2000. An unusually warm summer is defined as having an ATI higher than the mean value for the entire station record plus one standard deviation; an unusually warm winter is defined as having an AFI lower than the mean value for the entire station record minus one standard deviation.

Five stations exhibit both significant winter air temperature increases after 1970 and an unusually high frequency of warm winter events between 1981 and 2000. These stations are Fort Smith (Canada), Valdez (Alaska), and Verkhoyansk, Vilyuysk, and Yakutsk (central Russia). Four additional stations had a significantly high frequency of warm winter seasons between 1981 and 2000: Barrow and Nome (Alaska), and Salekhard and Turukhansk (central Russia). Two Greenland stations, Ammassalik and Nuuk, show clear evidence of a recent decrease in winter air temperatures.

Eight stations show evidence of significant recent summer air temperature increases in combination with a significantly high number of very warm summer seasons between 1981 and 2000 compared to the entire period of record. These are Barrow, Fairbanks, Nome, and Valdez (Alaska); Kuglutuk (Coppermine) and Fort Smith (Canada); Svalbard Airport; and Verkhoyansk (Central Russia). Bethel (Alaska) and Salekhard and Vilyuysk (central Russia) had a significantly high frequency of warm summer seasons between 1981 and 2000.

The two Greenland stations and Sodankylä (Finland) show evidence of recent air temperature decreases in both the mean ATI and the extreme summer values.

The results suggest a spatial pattern of recent climate change and are in agreement with results from other studies (e.g., AMAP, 1997). According to Table 16.3, temperatures have increased in central Russia, Alaska, and western Canada, while temperatures have decreased in southern Greenland. The trends are less clear in the Nordic countries and northwestern Russia.

16.2.2.3. Projected changes in permafrost

A constant rate of increase in air temperature is projected to have two related effects on ground temperature:

- an increase in the mean annual temperature at the ground surface, which will slowly propagate to greater depths and, depending on latitude, produce either a thinning or a complete disappearance of the permafrost layer; and
- changes in the annual amplitude of seasonal ground-temperature variation, damped with depth, and affected by related changes in precipitation (snow cover), groundwater hydrology, and vegetation. However, Riseborough (1990) pointed out that at temperatures close to 0 °C, latent heat effects may dominate and result in a smaller amplitude depending on the ice content of the soils.

Climate change is very likely to reduce the area occupied by frozen ground and to cause shifts between the zones of continuous, discontinuous, and sporadic permafrost. These changes can be projected using mathematical models of permafrost driven by scenarios of climate change. Projections of permafrost change in 2030, 2050, and 2080 using output from the five ACIA-designated climate models are presented in section 6.6.1.3.

The potential effects of increasing mean annual ground-surface temperature on permafrost will be very different for continuous and discontinuous permafrost zones. In the continuous zones, increasing air temperatures are very likely to increase permafrost temperatures and possibly increase the depth of the active layer (Burgess

Table 16.4. Comparison of maximum thaw depths simulated for 1990–1999 and 2090–2099 (Instanes A. and Mjureke, 2002b).

[a]Projection for 2040–2049.

et al., 2000a; Esch and Osterkamp, 1990; Osterkamp and Lachenbruch, 1990). In the discontinuous zone, the effects of a few degrees increase in the mean annual permafrost temperature are very likely to be substantial (Harris, 1986). Since the temperature of most of this permafrost is presently within a few degrees of the melting point, the permafrost is likely to disappear. Except for the southernmost zone of sporadic permafrost, many centuries will be required for the frozen ground to disappear entirely. However, increases in active-layer depth and thawing of the warmest permafrost from the top have already been observed (Burgess et al., 2000a; Esch and Osterkamp, 1990; Harris, 1986; Osterkamp and Lachenbruch, 1990).

Anisimov et al. (1997) used a permafrost model and climate scenarios for 2050 produced by general circulation models (GCMs) to project changes in active-layer thickness in the Arctic. The results of this study indicated that changes in active-layer thickness will vary by region, increasing by 10 to 15% to more than 50% between the mid-1990s and 2050. Instanes A. and Mjureke (2002b) used the ACIA-designated models (section 4.2.7) to project changes in active-layer thickness and maximum permafrost temperature for seven of the sites in Table 16.3: Barrow, Bethel, Naryan-Mar, Nuuk, Svalbard Airport, Turukhansk, and Verkhoyansk. The analysis used an identical soil profile with the same thermal properties for all the locations; therefore, it can only be used as an indication of relative climate differences between sites. The increase in maximum thaw depths between 1990–1999 and 2090–2099 and the changes in mean ground-surface temperature and soil bearing strength between 1990–1999 and 2090–2099 are presented in Tables 16.4 and 16.5, respectively.

The response of permafrost to climate change involves an important temperature threshold associated with phase change beyond which future temperature increases will cause thawing of the frozen ground. The time required to reach this temperature threshold depends on the initial permafrost temperature and the rate of temperature increase. Table 16.6 presents projected changes in various types of permafrost soils for different rates of warming.

The projections discussed in this section suggest that a progressive increase in active-layer depth and temperature of the frozen ground is likely to be a relatively short-term reaction to climate change in permafrost regions. Changes in seasonal thaw depth are very likely to change the water-storage capacity of near-surface permafrost at local and regional scales, with substantial effects on vegetation, soil hydrology, and runoff, which will ultimately lead to changes in larger-scale processes such as landslides, erosion, and sedimentation.

With respect to cold-regions engineering and infrastructure in locations affected by permafrost, the temperature of the frozen ground and the depth of seasonal thawing is of critical importance for effective construction planning and the evaluation of potentially hazardous situations at existing facilities. Although the effects of an increase in mean annual air temperature on permafrost can be projected in a general sense, it is more difficult to project these effects for specific locations and regions. Factors such as microclimate, as well as soil type, ice content, and salinity will play a role, and may not necessarily be well known or readily projected (Riseborough, 1990; Smith M. and Riseborough, 1983, 1985).

16.2.2.4. Projected changes in freezing and thawing indices

Freezing and thawing indices were calculated using mean monthly air temperatures projected for 2000 to

Table 16.6. Projected changes in permafrost soils between 2000 and 2100 for different rates of increase in mean annual air temperature and different soil types (Parmuzin and Chepurnov, 2001).

Warming trend (°C/yr)	T_{ini} (°C)	T_{2100} (°C)			Year thawing begins			Thaw depth in 2100 (m)

Peat								4–6	<5	<1.5

T_{ini}: initial mean annual temperature of permafrost soils; T_{2100}: mean annual temperature of permafrost soils projected for 2100.

2100 by the ACIA-designated climate models for the 21 stations shown in Table 16.3 (Instanes A. and Mjureke, 2002b). Output from four of the five ACIA-designated models (CGCM2 – Canadian Centre for Climate Modelling and Analysis, CSM_1.4 – National Center for Atmospheric Research, GFDL-R30_c – Geophysical Fluid Dynamics Laboratory, and HadCM3 – Hadley Centre for Climate Prediction and Research) was used for the analysis, along with a composite four-model mean (MEAN4).

In addition, results from empirical downscaling (Hanssen-Bauer et al., 2000) using the 2 m air temperature field from the ECHAM4/OPYC3 GSDIO integration (see section 4.6.2) were applied to Svalbard Airport.

Figures 16.3 and 16.4 show observed and projected freezing and thawing indices for Kugluktuk (Coppermine), Canada, from 1933 to 2100. The indices for 1933 to 2000 were calculated from meteorological observations, while the indices from 2000 to 2100 are based on output from the ACIA-designated models.

The figures show that the projections based on output from the different models "fit" the observed record to
Fig. 16.3. Observed and projected freezing indices for Kugluktuk (Coppermine), Canada (Instanes A. and Mjureke, 2002b).
Fig. 16.4. Observed and projected thawing indices for Kugluktuk (Coppermine), Canada (Instanes A. and Mjureke, 2002b).

varying degrees. This is one of the major problems with using GCMs for impact studies. However, indices computed using output from the different models show generally similar trends. This suggests that the raw model output can probably be adjusted so that computed indices start where the observations leave off, providing better projections of future trends in freezing and thawing indices.

Plots similar to Figs. 16.3 and 16.4 showing observed and projected freezing and thawing indices for the 21 stations in Table 16.3 are reported by Instanes A. and Mjureke (2002b).

16.2.2.5. Engineering concerns

The physical and mechanical properties of frozen soils are generally temperature-dependent, and these dependencies are most pronounced at temperatures within 1 to 2 °C of the melting point. Esch and Osterkamp (1990) summarize most of the engineering concerns related to permafrost warming as follows.

- Warming of permafrost body at depth.
    - a. Increase in creep rate of existing piles and footings.
    - b. Increased creep of embankment foundations.
    - c. Eventual loss of adfreeze bond support for pilings.
- Increases in seasonal thaw depth (active layer).
    - a. Thaw settlement during seasonal thawing.
    - b. Increased frost-heave forces on pilings.
    - c. Increased total and differential frost heave during winter.
- Development of residual thaw zones (taliks).
    - a. Decrease in effective length of piling located in permafrost.
    - b. Progressive landslide movements.
    - c. Progressive surface settlements.

Frozen-ground behavior

A constant rate of surface temperature increase due to projected climate change is very likely to lead to an increase in active-layer thickness. Woo et al. (1992), Kane et al. (1991), and Nakayama et al. (1993) attempted to simulate numerically the increase in active-layer thickness projected to result from climate change. Comparable simulations have been performed for three locations in the Mackenzie Basin, Canada (Burgess et al., 2000a).

In contrast to frozen rocks and dense gravels, whose strength depends mainly on mineral bonds and internal friction, the bulk of the mechanical strength of fine-grained frozen soils is due to ice bonding. Rising surface temperatures are likely to increase the unfrozen water content of fine-grained soils and decrease the ice bonding (cohesion) of soil particles, resulting in a gradual loss of strength in these soils.

Soil and rocks can be classified by their sensitivity to climate change, similar to the classification normally used in permafrost engineering. In order of increasing sensitivity (defined by the potential impacts of climate change on strength and thaw settlement), geological materials are classified as follows.

1. Rocks
   - dense, with ice only in pores; and
   - shattered, with ice filling cracks and fissures (an existing rock mass classification system can be used for evaluating the degree of fragmentation and fissures).
2. Gravels and sands (according to their density and moisture content).
3. Silts (according to their density and moisture content).
4. Clays (according to their density and moisture content).
5. Organic soils and peat.
6. Ground ice.

Andersland and Ladanyi (1994) provided a more detailed classification of frozen soils.

Frozen soil will settle to a certain extent when completely thawed. For a given soil type, the amount of thaw settlement can be related to the increase in active-layer thickness, the soil bulk or dry density, and its ice saturation or total water content. Several correlations between the unit thaw settlement and the physical properties of frozen soils have been published (Haas and Barker, 1989; Johnson et al., 1984; Johnston, 1981; Ladanyi, 1994; McRoberts et al., 1978; Nixon, 1990a; Speer et al., 1973). One such correlation relates the percentage of thaw settlement to the frozen bulk density and is the preferred methodology for engineering purposes (first published by Speer et al., 1973, and completed by Johnston, 1981). In the last

20 years, several such correlations between thaw settlement and frozen bulk density for a wide range of frozen soils have been published (Haas and Barker, 1989; Leroueil et al., 1990; Nelson R. et al., 1983), and some have also been expressed by empirical equations. "Thaw sensitivity maps" for specific permafrost regions can be created using information from climate models, surficial geology maps, organic soil maps, ground temperature data, and the above-mentioned correlations. Smith S. et al. (2001), Smith S. and Burgess (1998, 1999, 2004) and Nelson F. et al. (2002) have constructed such maps for Canada and the circumpolar Arctic.

The strength of frozen soil depends not only on temperature, but also on soil density, ice content, and salinity. It is also affected by the degree of confinement and the applied strain rate.
The sensitivity of frozen-soil strength to a temperature increase can be expressed by the ratio:

$$S_T = \frac{\Delta q_{fi}}{q_{fi}} \qquad \text{Eqn. 16.1}$$

where q_{fi} is the strength at temperature $\theta_i = -T_i$, and Δq_{fi} is its variation due to a temperature increase ΔT_i (see Fig. 16.5). The strength sensitivity index can also be expressed in terms of frozen soil creep parameters (Ladanyi, 1995, 1996, 1998).

The strength sensitivity index, S_T, defined in equation 16.1, may be a useful measure for evaluating the loss of strength in frozen soils in regions where climate change is not projected to cause complete permafrost thawing. The index requires information about the temperature sensitivities of strength and creep in typical arctic soils. Although some information already exists, further laboratory and field tests of permafrost soils are required. By combining information about permafrost occurrence, soil types and characteristics, and projected climate change, it may be possible to construct maps of projected effects on permafrost. Such maps would show not only the projected trends in active-layer depth and permafrost thawing, but also the projected reduction in permafrost strength. Permafrost sensitivity maps of this kind would be useful for projecting the effects of climate change on existing facilities in the Arctic, and for establishing guidelines for the design of new facilities. Vyalov et al. (1988) proposed the delineation of permafrost sensitivity zones in the Arctic, based on the mean annual ground temperature of permafrost (often measured at the level of negligible annual temperature amplitude, 10 to 20 m below the surface).

q = soil strength
q_f = soil strength of frozen ground
q_{th} = soil strength of thawed ground
q_{fi} = soil strength at a given temperature
$q_{fi} = q_{fi} - q_{f(i+1)}$ = change in soil strength for a specified temperature change, ΔT_i

Fig. 16.5. Variation in frozen-soil strength with temperature (Ladanyi, 1996).

Frost heave is the result of ice lenses developing as soils freeze. Temperatures below 0 °C and frost-susceptible soils are required for frost heave to occur, while the availability of water and the freezing rate determine the degree of frost heave. The first two

conditions generally do not differ much between permafrost and seasonal freezing regions. However, the availability of groundwater for ice accumulation in the active layer is different in the two regions. The active layer is generally thinner in permafrost regions, thus the freezing rate is rapid and there is less time available for ice lens growth. In addition, the presence of nearly impermeable permafrost below the active layer may limit the water available for lens formation in permafrost areas, so that for comparable soil conditions there is less frost heave in permafrost regions than in regions of seasonal freezing. An increase in the mean annual air temperature is very likely to increase the thickness of the layer subjected to freeze-thaw cycles and subsequent frost heave.

Thaw settlement and pile creep

An increase in the mean annual air temperature in permafrost regions is very likely to lead to an increase in the thickness of the active layer, resulting in increased thaw settlement during seasonal thawing; and is very likely to lead to a decrease in frozen-ground creep strength (long-term strength of frozen soil), resulting in an increase in the creep settlement rate of existing piles and footings.

Numerical simulations that assume a specific rate of warming have been used to project the degree of settlement effects on existing and future structures in the Arctic. Nixon (1990a,b, 1994) used a one-dimensional geothermal model and assumed a mean surface temperature increase of 0.1 ºC/yr for 25 years to examine the effects on thaw depth and pile creep settlement. The simulation of thaw depth below insulated surfaces in discontinuous permafrost projects a doubling of thaw depth after 25 years compared to a case with no temperature increase.

Thawing of permafrost soils can result in subsidence of the surface, thermokarst, and activation of freeze–thaw related processes such as solifluction. Parmuzin and Chepurnov (2001) projected soil subsidence in sandy loam soils by 2100 given different rates of warming and different soil ice content (Table 16.7). Other studies have projected the thaw settlement potential for Mackenzie Basin soils (Aylsworth et al., 2000; Burgess et al., 2000a; Burgess and Smith, 2003).

Such projections of the possible consequences of climate change may help inform the design of future facilities in permafrost regions.

16.2.2.6. Areas south of the permafrost border

In the Arctic and subarctic, there are large land areas south of the permafrost border that experience frost action during winter. Annual freezing of the top soil layer commonly causes frost heave of foundations and structures. Highway structures and embankments located above the frost-heave zone usually experience increased surface roughness and bumps (Andersland and Ladanyi, 1994). During the spring thaw, the bearing capacity of the structure may be considerably reduced, causing breakup of the pavement structure and failure of the embankment. It is possible that projected climate change will reduce the problems associated with winter frost action in these areas.

16.2.2.7. Summary

It is possible that projected climate change will be a factor in engineering projects if its effects go beyond those anticipated within the existing conservative design approach. Therefore, engineering design should take into account projected climate change where

Table 16.7. Projected soil subsidence between 2000 and 2100 due to the thawing of frozen deposits in sandy loam soils (Parmuzin and Chepurnov, 2001).

Initial (2000) permafrost soil temperature (°C)	Volumetric ice content of soil (%)	Air temperature increase (°C/yr)

appropriate and where the potential effects represent an important component of the geothermal design.

The sensitivity of permafrost soil strength to projected climate change can be mapped using a simple strength sensitivity index, such as the one proposed in this section. A risk-based procedure for analyzing structures based on their sensitivity to the potential consequences of climate change is a reasonable approach to incorporating climate change concerns into the design process (section 16.4.1). The project-screening tool developed and currently in use in Canada is a very good guideline for such an approach (Bush et al., 1998).

16.2.3. Natural hazards

In some regions of the Arctic, climate change is projected to lead to increasing temperature and precipitation (sections 4.4.2, 4.4.3, and 6.2.3) and increasing storm frequency (Hanssen-Bauer and Forland, 1998). The type of precipitation is very likely to change as the temperature increases. Where the average winter temperature is close to 0 ºC, a higher frequency of precipitation falling as rain instead of snow is expected. Runoff from the arctic river basins is likely to increase due to greater snow depth resulting from increased winter precipitation and to increased thawing of permafrost resulting from surface warming in summer. Greater winter snow depth coupled with rapid melting caused by higher spring temperatures is likely to increase the possibility of floods in the arctic river basins and increase erosion in thawing permafrost riverbanks. Thawing permafrost and increasing depth of the thawed layer are likely to make slopes vulnerable to slides caused by erosion, increasing pore water pressure, and earthquakes.

Floods and slides in soil, rock, and snow are directly or indirectly connected to weather phenomena. Slides in soil and rock can also be triggered by earthquakes. Most structures in the Arctic are located and designed based on historic observations of extreme weather events to meet defined criteria for acceptable risk. Climate change is very likely to change the probability of natural hazard occurrences. This implies that criteria for the location and design of infrastructure must be revised to keep risks at defined levels.

16.2.3.1. Infrastructure and natural hazards

Settlements are often located in areas of low hazard risk to avoid floods, mudflows, slides, and avalanches. River embankments are designed to control rivers during extreme flood events. The location and design of communities and structures are determined based on the risk of hazard occurrence (e.g., permanent settlements in Norway are only permitted in areas where the annual probability of natural hazards is less than 1×10^{-3}). Highways and railways crossing steep terrain are located where the risk of closure and accidents due to natural hazards is acceptable, or can be mitigated by protection facilities (e.g., snow sheds).

Houses, highways, roads, railways, transmission lines, and other infrastructure are sometimes located in areas exposed to snow accumulation and drifting. Highways and railways may be subjected to traffic restrictions or closure by high wind velocities and related snow drifting. To avoid dangerous snow accumulation, regulations in some areas dictate that houses and transmission lines are located in terrain where snow depths are acceptable or appropriate protection has been installed. At present, regulations governing the design of these facilities are based on acceptable risks of extreme snow depth, ice loads, wind forces, and storm frequencies.

16.2.3.2. Factors affecting slope stability and failure

Acceptable risk is directly related to the probability of slides and avalanches. Factors important to slope stability include the groundwater regime, and erosion caused by surface water flow, freeze–thaw processes, and human activity. The groundwater regime is affected by precipitation and meltwater infiltration. For a specific slope, the probability of slides can often be related to threshold values for water infiltration caused by the intensity and duration of rain and snowmelt.

Snow accumulation in avalanche release areas in mountainous regions of the Arctic (Scandinavia, Iceland, Russia, and North America) is dependent on wind velocity and duration in addition to the intensity of snowfall. Avalanche probability depends primarily on the rate of snow accumulation in the release area. The probability of slush avalanches (where water-saturated snow releases as a slide) is related to the porosity and permeability of the snow, which play a key role in snow stability. Slush avalanches release when the rate of water infiltration by rain and snowmelt reaches a threshold value for the specific type of snow on the slope.

Thawing of permafrost caused by climate change will possibly also influence the stability of a particular site. As shown in section 16.2.2.5, the strength of frozen soil drops rapidly as the temperature rises above 0 ºC. The development of a weak saturated layer between frozen and unfrozen material can trigger landslides; slopes along arctic rivers are particularly sensitive to failure due to erosion of the toe of the slope (Dyke et al., 1997; Dyke, 2000). Such landslides are known as active-layer detachment slides or skin flows, which can also be triggered by forest fires that burn away the insulating organic layer, leading to increased absorption of solar radiation and more rapid thaw of the active layer.

Reservoirs are used to control flooding in some watersheds, but most arctic watersheds are unregulated. Flood intensity is dependent on precipitation and snowmelt rates and is tempered by the ability of the soil ability to absorb water.

Mudflows and debris flows are triggered as a consequence of a rapid increase in pore water pressure

together with runoff-induced erosion (Sandersen et al., 1996). They occur during periods of intense rainstorms or as a consequence of rapid melting of snow and ice. Severe mudflows can also occur as a result of rapid drainage of glacier-dammed lakes due to glacial melting; examples of this phenomenon include the catastrophes in the Sima Valley (Norway) in 1893 and 1937, and in the city of Tyrnyauz (Caucasus) in 1977 and 1992 (Seinova, 1991; Seinova and Dandara, 1992).

16.2.3.3. Potential impacts of climate change on avalanche and slide activity

The ACIA-designated climate models forced with the B2 emissions scenario project that mean annual arctic temperatures (60º–90º N) will increase 1.2 ºC by 2011–2030, 2.5 ºC by 2041–2060, and 3.7 ºC by 2071–2090 compared to the 1981–2000 baseline (5-model average, see section 4.4.2). The increase is projected to have an uneven spatial distribution, with the greatest increase in the Russian and Canadian Arctic, and the smallest increase in areas close to the Atlantic and Pacific coasts (IPCC, 2001). The changes are also projected to vary seasonally, with the greatest temperature increases occurring in winter.

The Norwegian Meteorological Institute projects that temperatures in Norway will increase by 0.2 to 0.7 ºC between 2000 and 2010. The greatest increase is projected to occur in part of the Norwegian Arctic in winter (Haugen and Debenard, 2002). Regional downscaling of temperature projections for other regions of the Arctic has not been performed, but would be useful for assessing the potential impacts of climate change on natural hazards.

As a consequence of rising temperatures, the ACIA-designated models project average increases in precipitation of 4.3% by 2011–2030, 7.9% by 2041–2060, and 12.3% by 2071–2090 compared to the 1981–2000 baseline (section 4.4.3). Precipitation increases are projected to be greatest in winter, and smallest in summer (when a decrease is projected for some Russian watersheds).

Changes in the extent of snow cover in the Arctic are very likely to be influenced by both temperature and precipitation. Increasing temperature in a region is very likely to lead to earlier spring snowmelt and reduced snow cover extent at the end of the winter. Conversely, increasing precipitation is very likely to lead to greater snow depth in winter, especially in the coldest parts of the region. The ACIA-designated models project decreases in arctic snow-cover extent of 3–7%, 5–13%, and 9–18% by 2011–2030, 2041–2060, and 2071–2090, respectively, compared to the 1981–2000 baseline (section 6.4.3). The decrease in snow extent between the baseline (1981–2000) and 2071–2090 is projected to be greatest in spring (4.9 x 10^6 km^2) and winter (3.8 x 10^6 km^2), and lowest in summer (1.1 x 10^6 km^2) and autumn (3.3 x 10^6 km^2).
Fig. 16.6. Storm track activity (geopotential meters – gpm) over northwest Europe projected by the ECHAM4/OPYC greenhouse-gas scenario (4-yr running mean). The non-linear climate trend obtained from quadratic curve fitting is marked by the smooth curve (Ulbrich and Christoph, 1999, cited in IPCC, 2001).

Storms also affect avalanche and slide activity, and are projected to increase in frequency (5 to 10%) and amplitude over the 21st century (IPCC, 2001; see Fig. 16.6). For the west coast of Norway, the Norwegian Meteorological Institute projects a higher frequency of storms and greater amplitudes of storm activity over the next 50 years, combined with a 20% precipitation increase and a temperature increase of 2 to 3 ºC, with the greatest change occurring in winter (Hackett, 2001; Haugen et al., 1999).

Avalanche activity depends on the rate of snow accumulation, which is dependent on temperature (<0 ºC), precipitation rate, and storm frequency. A change in any of these factors is very likely to have an impact on avalanche activity. Increasing snow precipitation is likely to occur in areas with continental climates and high-altitude coastal regions, leading to an increase in avalanche activity. For example, an increase in precipitation rates and storm magnitude is likely to increase snow accumulation intensity in high-altitude avalanche release areas. Because avalanche run-out distance is related to the volume of snow released, it is possible that greater snow accumulation will cause longer run-outs than have historically occurred, resulting in increased risk to settlements and infrastructure.

As snow accumulation primarily occurs at temperatures below 0 ºC, snow-cover extent and depth will depend on the duration of the frost period and the precipitation environment in any given area. In regions of the Arctic with long cold periods and low precipitation, changes in temperature and precipitation will have a negligible influence on avalanche activity. Conversely, in regions where winter temperatures are presently close to 0 ºC and precipitation rates are high, the snow environment has a high sensitivity to changes in climate. For example, Naryan-Mar in northwest Russia (67.6º N, 53º E) has a typical arctic continental climate, with an average January temperature of -18.9 ºC and a snow cover less sensitive to temperature change than Vardø in Norway (70.37º N, 31.1º E), which has a typical maritime climate and an average January temperature of -5.1 ºC.

In the continental Russian, Canadian, and Alaskan regions of the Arctic, the winter is long and cold, with few periods of temperature above 0 °C. The coastal areas of Scandinavia and Iceland and the west coast of North America have shorter and warmer winters with a higher frequency of temperature fluctuations around 0 °C. A winter temperature change of a few degrees in cold continental regions of the Arctic is very likely to affect the duration of the winter, but not very likely to affect the snow environment.

As temperature is dependent on altitude, mountain areas with relatively low average temperatures are very likely to be less affected by temperature change than lower-elevation coastal areas. At low altitudes in a warmer maritime climate such as that of Scandinavia, the frequency of precipitation falling as rain is very likely to increase in the future. The frequency of snow avalanches with release areas at low altitudes (below 500 to 1000 m) is likely to be reduced due to this change in precipitation type. Increases in the frequency of rainstorms and intensity of storm precipitation are likely to lead to an increasing frequency of mudflows, as well as an increasing frequency of slush flows where the rate of thaw together with intense rain precipitation is the triggering mechanism (Hestnes, 1994). A higher frequency of winter rain events is very likely to increase the number of wet snow and slush avalanches. However, the duration of slush flow activity in the Arctic is projected to be shorter (Sidorova et al., 2001). The frequency of mudflows and debris flows is projected to increase, as the summer season is projected to be longer, with greater amounts of precipitation and a higher frequency of extreme events such as rainstorms and storm-induced flooding (Glazovskaya and Seliverstov, 1998). For Iceland, storm frequency and precipitation falling as rain are projected to increase along the east coast and decrease along the west coast, owing to a reduction in the ice sheet along the Greenland coast (Olafsson, pers. comm., University of Iceland, Reykjavik, 2003).

In maritime climates, the frequency of avalanches with long run-out distances is likely to decrease, owing to a projected change in snow type (from dry-snow to wet-snow and slush avalanches). This is very likely to have a positive effect on transportation routes in some areas. As the frequency of dry-snow avalanches with long run-out distances decreases, the exposure of highways and buildings to avalanches will be reduced.

Increased precipitation is projected to influence groundwater flow. Higher temperatures will probably also increase the thaw rate in spring and summer, increasing groundwater flow and flood potential. In low-altitude areas where snow is presently the predominant form of winter precipitation, an increase in winter rain events is likely to lead to a higher probability of slides in rock and soils (Fig. 16.7). Slopes that are stable under the current precipitation regime are likely to gradually become unstable if the frequency and magnitude of rainstorms increase (Sandersen et al., 1996), leading to a potential increase in rock and soil slide activity until a new equilibrium is established.

A change in the groundwater regime is also likely to affect the pore water pressure in quick clays (materials that can change rapidly from solid to liquid state) that are typical of some fjord districts in the Scandinavian and Canadian Arctic (Bjerrum, 1955; Janbu, 1996; Larsen et al., 1999), and may cause instability of these materials. Quick-clay slides (Fig. 16.8) have caused serious disasters with loss of lives and properties. Together with increased floods and erosion by rivers, higher amounts of groundwater are very likely to increase the risk of quick-clay slides in the future.

As shown in sections 6.6.1.2 and 6.8.2, observed air temperature changes in the Arctic have increased the thaw depth in permafrost areas and increased the discharge of water to the Arctic Ocean from Eurasia (Shiklomanov, et al., 2002). These changes are causing numerous slides in permafrost riverbanks (Fig. 16.9).

Increasing storm frequencies are very likely to increase closure periods of wind-exposed roads, highways, railroads, and airports, and are likely to affect industries and other human activities dependent on transportation. For example, an increase in the frequency of closed roads is very likely to have an impact on the fishing industry in Norway where immediate transport of fresh fish to the European market is essential.

Greater amounts of precipitation combined with increased rates of snowmelt is likely to increase water infiltration in rock and influence the cleft water pressure in tension cracks in high mountain slopes (Terzaghi, 1963). The cleft water pressure depends on the permeability of the rock and the rate of infiltration; higher cleft water pressures can increase the probability of landslides in hard rock (Fig. 16.10).

16.2.3.4. Summary

Climate change is projected to increase precipitation frequencies and magnitudes, and it is possible that the frequency and magnitude of storms will increase in some regions. An increase in the frequency and magnitude of storms is very likely to lead to increased closures of roads, railways, and airports. Increases in temperature and precipitation together with increases in storm magnitude and frequency are very likely to increase the frequency of avalanches and slides in soil and rock. In some areas, the probability that these events will affect settlements, roads, and railways is likely to increase. Structures located in areas prone to slope failure are very likely to be more exposed to slide activity as groundwater amounts and pore water pressure increase. It is possible that floods of greater magnitude will occur due to greater amounts of precipitation and higher rates of snowmelt. Increased erosion due to higher river flows and thawing permafrost is very likely to initiate slope failure in riverbanks, exposing infrastructure such as buildings, harbors, and communication lines to potential damage. In low-altitude areas with maritime climates, increased temperatures and more precipitation falling as rain are likely to result in a higher frequency of wet-snow avalanches where dry-snow avalanches dominate at present. This is likely to reduce avalanche run-out distance and related problems on exposed traffic routes. The frequency and extent of slush-flow avalanches are likely to increase in the future. An increasing probability of slides coupled with increases in traffic and population concentrations is very likely to lead to expensive mitigation measures to maintain a defined risk level. The best way to address these problems is to incorporate the potential for increasing risk in the planning process for new settlements and transportation routes such as roads and railways.

16.2.4. Coastal environment

The Arctic has approximately 200 000 km of coastline, most of which is uninhabited. However, coastal development is critical to the economy and social well-being
Fig. 16.11. Processes affecting bluff erosion in Cook Inlet, south-central Alaska (redrawn from Smith O. and Levasseur, 2002).

of nearly all arctic residents (see also Chapters 3, 12, and 15). Natural-resource development is concentrated along the coast, and the development of resources in these remote areas is constrained because of challenging transportation routes (Smith O. and Levasseur, 2002).

Arctic coastal dynamics are often affected directly or indirectly by the presence of permafrost. Permafrost coasts are especially vulnerable to erosive processes as ice beneath the seabed and shoreline melts from contact with warmer air and water. Thaw subsidence at the shore allows additional wave energy to reach unconsolidated erodible materials. Low-lying, ice-rich arctic permafrost coasts are the most vulnerable to thaw subsidence and subsequent wave-induced erosion.

The southern half of Alaska has coastal characteristics dominated by erodible glacial deposits and high tides. Cook Inlet, in south-central Alaska, has a 10 m tidal range at its northern extreme and an eroding shoreline of glacially deposited bluffs, as illustrated in Fig. 16.11 (Smith O. and Levasseur, 2002). Freezing of brackish water and ice deposition on broad tidal flats create huge blocks of "beach ice" (Fig. 16.12) that, when set afloat by higher tides, can carry coarse sediments for distances of over a hundred kilometers. Of all Cook Inlet sea ice, these sediment-laden ice blocks present
the greatest danger to ships in winter. The complex dynamics of bluff erosion and ice-borne sediment transport will become even more difficult to forecast with sea-level rise and a more erratic storm climate.

16.2.4.1. Observed changes in the coastal environment

Coastal erosion rates vary considerably across the Arctic. As indicated in Fig. 16.13, erosion rates are dependent on environmental forcing, sedimentology, geocryology, geochemistry, and anthropogenic disturbance of the coastline. In fine-grained icy silty–clayey sediments, average erosion rates are typically 1 to 3 m/yr, while in silty–sandy sediments with high ice content that are directly exposed to waves and storm surges, erosion rates can be as high as 10 to 15 m/yr under extreme weather conditions. Frozen rock and sediments with low ice content may have erosion rates as low as 0.1 m/yr. Anthropogenic disturbance of the coastline can increase erosion rates, but there are also examples from Varandei in the Pechora Sea indicating that shore protection techniques can slow erosion rates. Table 16.8 presents examples of erosion rates along the arctic coast.

Erosion rates have increased along the arctic coast over the past 30 years. Coastal residents are concerned about the observed changes and the future of arctic coastal communities. However, arctic coastal survey data are often inadequate to reliably quantify accelerating shoreline retreat. Baseline surveys using satellite imagery will help the assessment of erosion rates and systematic planning of future responses significantly. Understanding of circumpolar coastal dynamics is also inadequate. Improved understanding of the physical processes involved in arctic coastal erosion will improve techniques for shore protection and other mitigation measures that may be necessary in the future.

The Arctic Coastal Dynamics project (ACD) is a recent international initiative, sponsored by the International Arctic Sciences Committee and the IPA, to address coastal change in the Arctic (Rachold et al., 2002,

Fig. 16.12. Beach ice in macro-tidal zones of Alaska (photo provided by Orson Smith, University of Alaska, Anchorage).

Fig. 16.13. Processes affecting coastal erosion in the Arctic (redrawn from Rachold et al., 2002).

2003). Its objective is to improve the understanding of coastal dynamics as a function of environmental forcing (including climate change), coastal geology and cryology, and changes in landforms (Fig. 16.13). The ACD has proposed:

- to establish the rates and magnitudes of erosion and accumulation along arctic coasts (e.g., Table 16.8);
- to develop a network of long-term monitoring sites including local community-based observation sites; and
- to develop empirical models to assess the sensitivity of arctic coasts to environmental variability and change and human impacts.

Output from studies such as those proposed by the ACD can be used for site-specific evaluation of arctic coastal areas. This type of research and monitoring is essential to document ongoing and future changes and to make policy recommendations.

16.2.4.2. Projected changes in the coastal environment

Arctic coastal conditions are likely to change as climate changes. Thinner, less extensive sea ice is very likely to improve navigation conditions along most northern shipping routes, such as the Northwest Passage and the Northern Sea Route (see also section 16.3.7). However, decreasing sea-ice extent and thickness is very likely to affect traditional winter travel and hunting where sea ice has been used for these purposes.

Greater expanses and longer periods of open water are likely to result in wave generation by winds over longer fetches and durations. Wave energy is constrained by wind speed, duration of winds, extent of fetch, and water depth. Wave-induced coastal erosion along arctic shores is likely to increase as climate changes. Sea-level rise and thaw subsidence of permafrost shores are projected to exacerbate problems of increased wave energy at the coast. If more frequent and intense storms accompany climate change, these are also likely to contribute to greater wave energy.

Global sea level is rising, although the contribution of various factors to this rise is still being debated (section 6.9.2). The volume of water in the oceans is increasing due to thermodynamic expansion of seawater and melting of ice caps and glaciers. Rising sea level inundates marshes and coastal plains, accelerates beach erosion, exacerbates coastal flooding, and increases the salinity of bays, rivers, and groundwater. Some northern regions, such as the southern coasts of Alaska, have sea-level trends complicated by tectonic rebound of the land resulting from the retreat of continental glaciers at the end of the last glacial period. At Sitka, in south-

east Alaska, the net effect is falling sea level. However, arctic coasts have a wide variation of tectonic trends. Low-lying coastal plains in the Arctic are generally not tectonically active, which is another reason why they are vulnerable to the adverse effects of sea-level rise. Global sea-level rise will possibly allow more wave energy to reach the coast and induce erosion as waves break at the shore.

Reduced sea-ice extent and thickness are very likely to provide opportunities for the export of natural resources and other waterborne commerce over new northern shipping routes. Reduced sea ice in the coastal regions of the Arctic Ocean is very likely to result in longer navigation seasons along the Russian Arctic coast, in the Canadian Arctic, along the eastern and western coasts of Greenland, and around Alaska. Enhanced regional arctic navigation, such between Europe and the Kara Sea, and potential trans-arctic voyages using icebreaking container ships and tankers, is very likely to shorten distances between markets and improve the delivery times for valuable products.

Climate change is also likely to change the use of arctic rivers for transportation routes, water sources, and habitat. Increased precipitation is very likely to result in higher stream flows and more flooding. Conditions for commercial river navigation will possibly improve the transport of minerals and bulk exports to tidewater. Erosion of thawing permafrost banks is very likely to accelerate, threatening the infrastructure of rural arctic river communities. River-ice breakup is very likely to occur earlier and ice jams and flooding risks are likely to be more difficult to project. The projection and prevention of ice-jam flooding warrant further study.

Higher sea levels at the mouths of rivers and estuaries are likely to allow salt to travel further inland, changing riparian habitats. Furthermore, climate change is projected to result in more frequent and intense storms accompanied by stronger winds. These winds are very likely to induce even higher water levels at the coast, accompanied by higher waves. Storms are also

likely to result in more intense rainfall at the coast, increasing runoff-related erosion and the mobile sediment in coastal waters.

Coastal communities are sensitive to climate change. Engineering solutions are available for shore protection (flood barriers, dikes, breakwaters, erosion control) but may not be able to reduce erosion rates sufficiently to save specific settlements. Moreover, while these protective measures may address one problem, they may create another by altering the dynamics of erosion and deposition processes.

16.2.5. Arctic Ocean

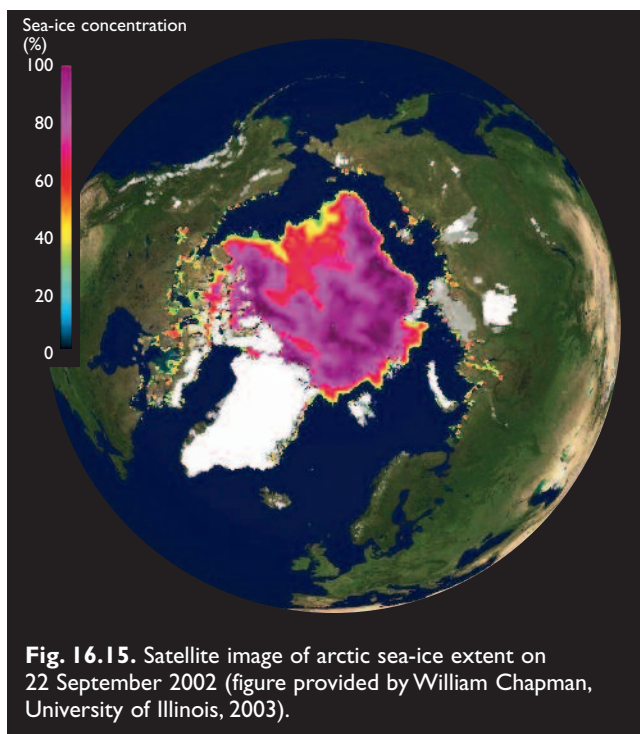
16.2.5.1. Observed changes in sea-ice extent

Climatic and environmental changes in the Arctic Basin include changes in air temperature, water temperature and salinity, and the distribution, extent, and thickness of sea ice. There is compelling empirical evidence of consistent environmental changes across the Arctic Ocean, including increases in air temperature, reductions in sea-ice extent, and freshening of the Beaufort Sea mixed layer (Maslanik et al., 1996; McPhee et al., 1998). Data from ice-floe measurements show a slight air temperature increase with statistically significant warming in May and June between 1961 and 1990. Air temperature anomalies in the Arctic Basin have been strongly positive since 1993. Between 1987 and 1997, the mean annual air temperature increased by 0.9 ºC (Aleksandrov and Maistrova, 1998), comparable to temperature changes observed in the terrestrial Arctic.

The area of warm Atlantic waters in the polar basin increased by almost 500 000 km^2 over the past three decades (Kotlyakov, 1997), and the inflowing freshwater has warmed (Carmack, 2000; Carmack et al., 1995). Measurements from submarines indicate that surface waters in the Arctic Ocean basin warmed by 0.5 to 1 ºC from the mid-1970s to the mid-1990s, with maximum warming observed in the Kara Sea (Alekseev et al., 1997).

One of the most valuable and graphic records of sea-ice extent changes in the Northern Hemisphere was produced by Walsh and Chapman (2001). Figure 16.14 shows a 103-year record (1900–2002) of sea-ice extent. A decreasing trend in sea-ice extent, starting in the mid-20th century, is evident for all four seasons. The greatest decreases have occurred in summer and spring: over the past 50 years, summer sea-ice extent has decreased by nearly 3 x 10^6 km^2. Although the decrease in sea-ice extent has been unevenly distributed around the coastal margins of the Arctic Ocean, it has provided greater marine access for ships.

Satellites have recorded increasing areas of open water along the Russian Arctic coast and in the Beaufort Sea. Figure 16.15 is a satellite passive microwave image showing the extent of arctic sea ice on 22 September
Fig. 16.14. Sea-ice extent in the Northern Hemisphere between 1900 and 2002 (Walsh and Chapman, 2001, updated).

Fig. 16.15. Satellite image of arctic sea-ice extent on 22 September 2002 (figure provided by William Chapman, University of Illinois, 2003).


2002 – the date of the minimum observed extent in the 103-year record. This image illustrates the large areas of open water surrounding the Arctic Basin at the summer minimum extent of sea ice. Of significance for the Northern Sea Route, the only pack ice reaching the Russian Arctic coast is along the northern tip of Severnaya Zemlya; the sea ice in this image has also retreated record distances in the Beaufort, Chukchi, and East Siberian Seas.

Sea-ice conditions in the Canadian Arctic are very complex. Observations of minimum sea-ice extent in the eastern and western regions of the Canadian Arctic between 1969 and 2003 (Fig. 16.16) illustrate the extraordinary interannual variability of the ice conditions. Although the trends in sea-ice extent are negative in both regions over the period shown, the year-to-year variability is extreme and sometimes differs between the two regions. For example, one of the largest observed minimum extents in the western region (for the period shown) occurred in 1991, while in the eastern region the minimum sea-ice extent that year was relatively low. While these observations indicate a recent overall decrease in the extent of sea ice in the Northwest Passage, the interannual and spatial variability is not conducive to planning a reliable marine transportation system.

16.2.5.2. Projected changes in sea-ice extent

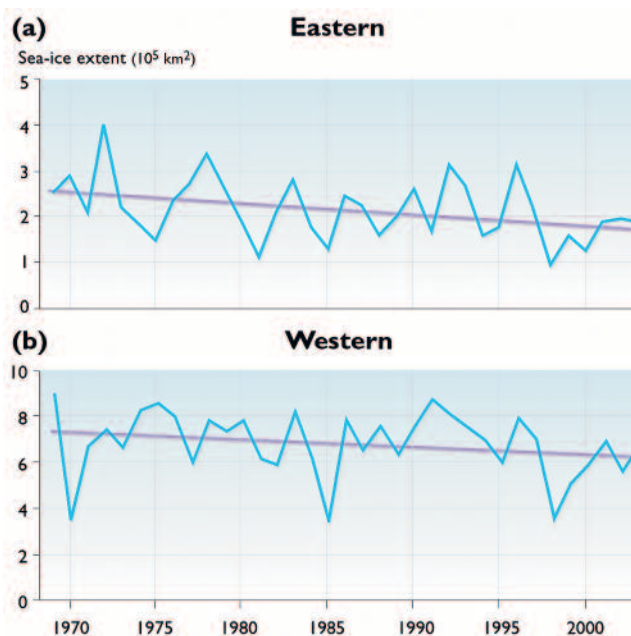
Figure 16.17 shows the median of the sea-ice extents projected by the five ACIA-designated climate models for the three ACIA time slices. However, an important limitation of the ACIA-designated models is that they cannot resolve the complex geography of the Canadian Arctic and thus cannot provide adequate sea-ice projections for this region. In summer, the models project a substantial retreat of sea ice throughout the entire Arctic Ocean for each ACIA time slice, except for parts of the Canadian Archipelago and along the northern coast of Greenland. By mid-century (September 2041–2060), most of the alternative routes in the Northwest Passage and Northern Sea Route are projected to be nearly ice-free; three of the five models project open water conditions across the entire lengths of both. By the end of the 21st century, vast areas of the Arctic Ocean are projected to be ice-free in summer, increasing the possibility of shipping across the Arctic Ocean.


Fig. 16.16. Annual minimum sea-ice extent in (a) the eastern and (b) the western regions of the Canadian Arctic between 1969 and 2003, from a composite of remotely sensed and ground-based measurements. Lavender lines show linear trends (redrawn from figure provided by the Canadian Ice Service, 2004).
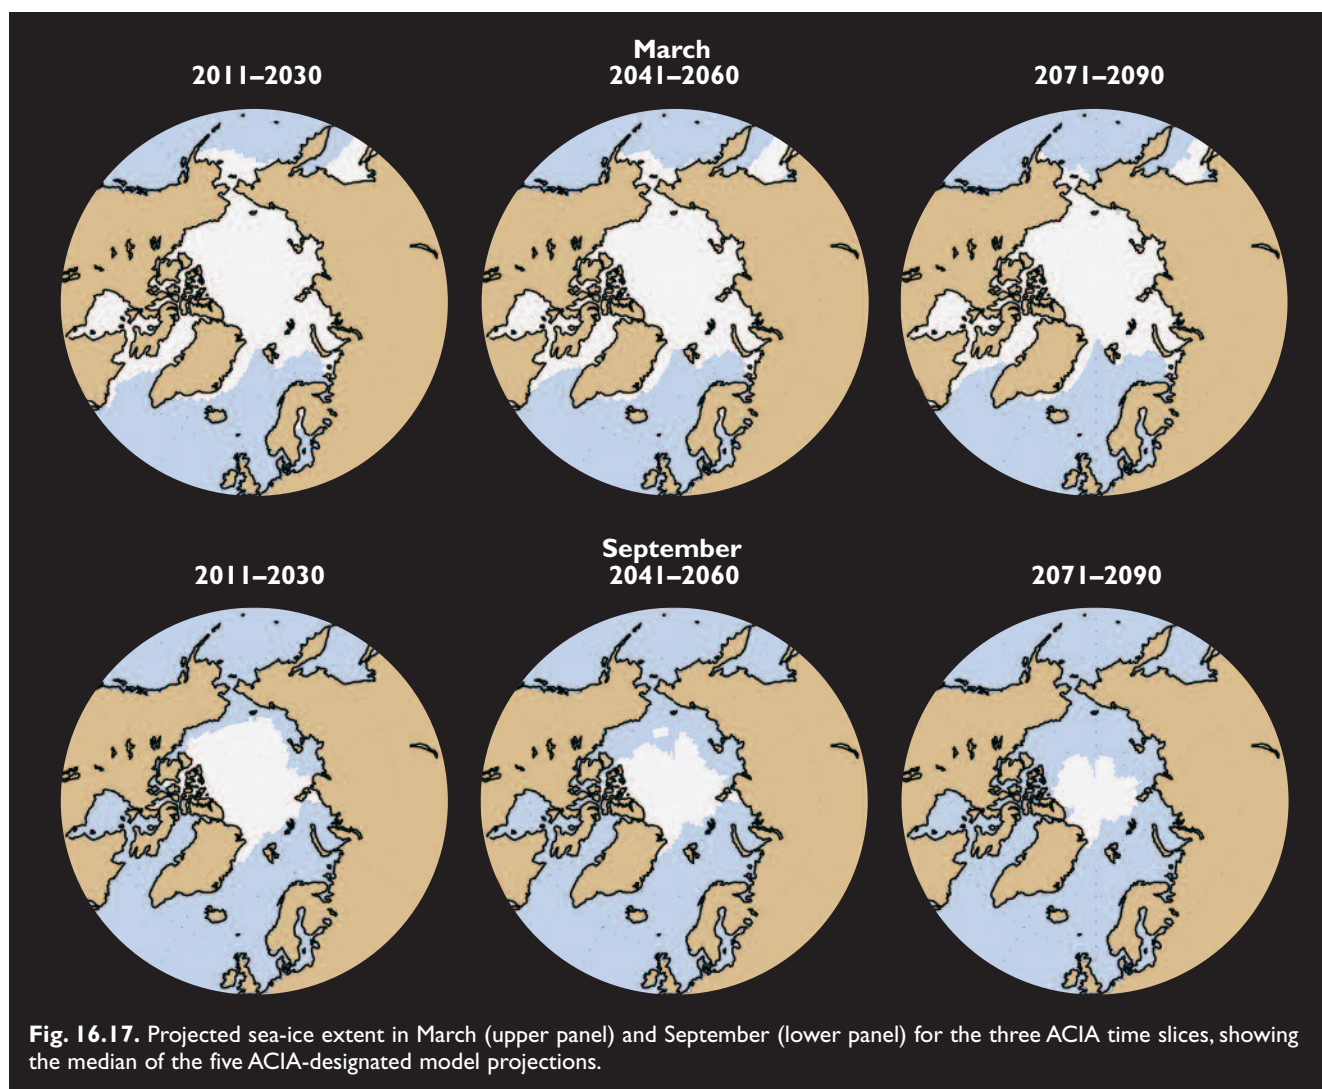

Fig. 16.17. Projected sea-ice extent in March (upper panel) and September (lower panel) for the three ACIA time slices, showing the median of the five ACIA-designated model projections.

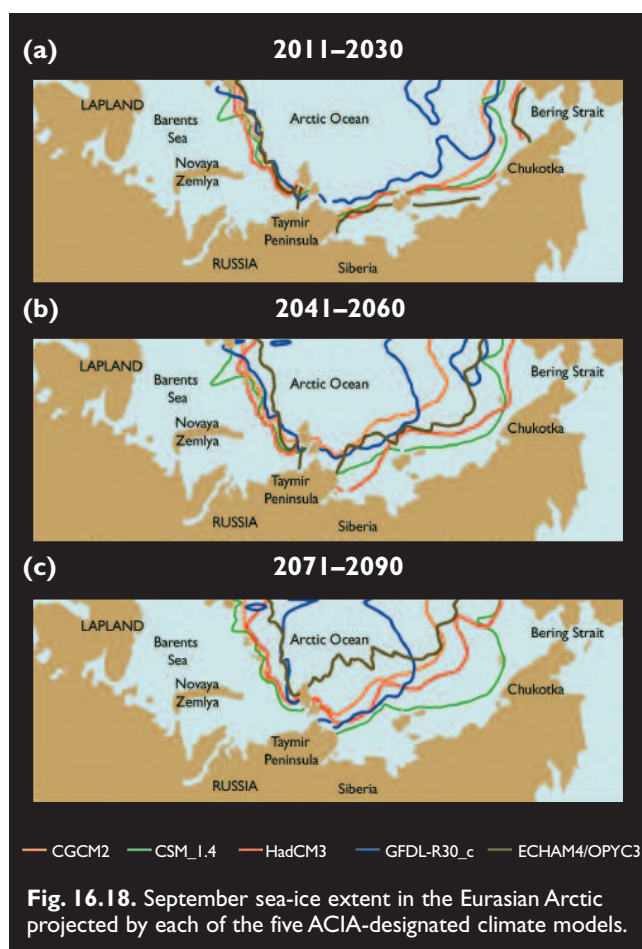
Although there is some projected winter retreat of the sea-ice edge, particularly in the Bering and Barents Seas where ship access is likely to improve throughout the 21st century, most of the Arctic Ocean is projected to remain ice-covered in winter. However, sea-ice cover is likely to be on average thinner, and the area of multi-year sea ice in the central Arctic Ocean is likely to decrease through 2080. Winter navigation (throughout the year to Dudinka since 1978) along the western end of the Northern Sea Route, from the Barents Sea to the mouths of the Ob and Yenisey Rivers, will possibly encounter less first-year sea ice. Full transit of the Northern Sea Route through Vilkitskii Strait to the Bering Sea is very likely to remain challenging and require icebreaker escort. The only improvement in winter sea-ice conditions for the Laptev, East Siberian, and western Chukchi Seas is a possible reduction in the area and frequency of multi-year floes along the navigable coastal routes.

The significant interannual sea-ice variability in the arctic seas is also important to navigation. The projected increase in ice-free areas and reduced sea-ice concentrations will possibly lead to a more dynamic sea-ice cover under the influence of local and regional wind fields. These more variable environmental condi-

tions, combined with an increase in the number of ships making passages in the Arctic Ocean, will possibly lead to a higher demand for sea-ice information, long-range ice forecasting, and increased icebreaker support. While direct (across the North Pole) trans-arctic voyages are unlikely by mid-century, voyages may be possible north of the arctic island groups (such as those along the Russian Arctic coast) and away from shallow continental shelf areas that restrict navigation.

There is likely to be an increased requirement for real-time satellite imagery of sea-ice conditions. Increased ship access to the Arctic Ocean is very likely to require more resources to facilitate marine traffic and to support maritime safety and protection of the arctic marine environment.

The four ACIA regions are not conveniently drawn for assessment of future arctic marine transport routes. Therefore, as a case study, a new "sector" was defined between 60º and 90º N, and between 40º E and 170º W, which includes the coastal region from the eastern Barents Sea to Bering Strait. This sector also encompasses Russia's Northern Sea Route, defined by regulation as the routes or waterways between Kara Gate (at the southern end of Novaya Zemlya) and Bering Strait.

Fig. 16.18. September sea-ice extent in the Eurasian Arctic projected by each of the five ACIA-designated climate models.


As shown in Fig. 16.17, the median of the ACIA-designated model projections suggests that, in all the time slices, most coastal waters of the Eurasian Arctic (along the Northern Sea Route) will be relatively ice-free in September. Figure 16.18 illustrates the September sea-ice extents projected by each of the five models for the Eurasian Arctic sector used in this analysis. During September, the month of minimum sea-ice extent in the Arctic Ocean, the models consistently project sea ice in the vicinity of Severnaya Zemlya during each of the ACIA time slices. For ships to travel north of Severnaya Zemlya, highly capable, more expensive icebreaking ships would be necessary. However, it is more likely that ships would sail through the deep waters of Vilkitskii Strait to the south – between the Kara and Laptev Seas north of the Taymir Peninsula – where more open water is very likely to be found. Four of the five models also project open water to the east and north of the New Siberian Islands in September. Ships sailing along the Northern Sea Route are likely to take advantage of these ice-free conditions to avoid the shallow, narrow passages along the Eurasian coast. In addition, if there is a continued reduction in the proportion of winter multi-year sea ice in the Central Arctic Ocean (Johannessen et al., 1999), it is very likely that first-year sea ice will dominate the entire maritime region of the Northern Sea Route throughout the year, with a decreasing frequency of intrusions of multi-year sea ice into the coastal seas. Such changes in sea-ice conditions would have key

implications for ship construction (e.g., potentially lower construction costs) and route selection along the Northern Sea Route in summer and winter.

16.3. Infrastructure in the Arctic

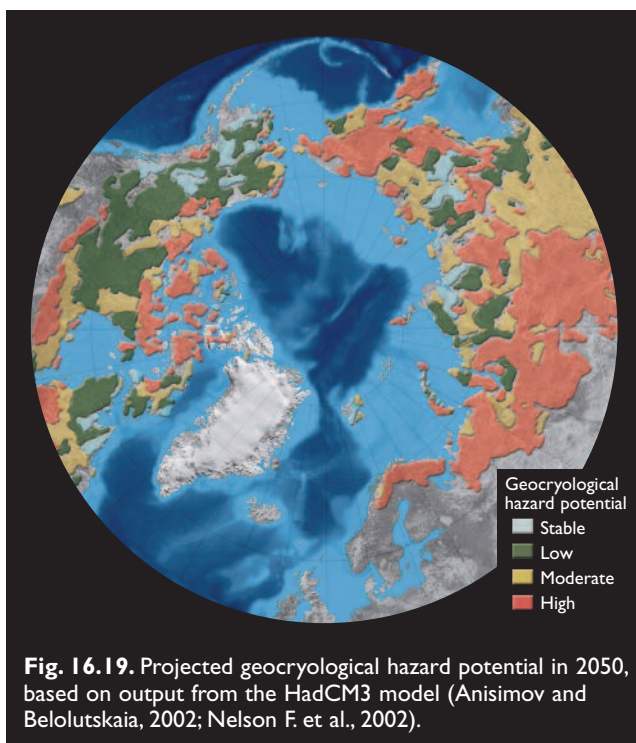
Infrastructure is defined as facilities with permanent foundations or the essential elements of a community. It includes schools; hospitals; various types of buildings and structures; and facilities such as roads, railways, airports, pipelines, harbors, power stations, and power, water, and sewage lines. Infrastructure forms the basis for regional and national economic growth. In the Arctic, the largest population concentrations are located in North America and Russia (Freitag and McFadden, 1997), as is much of the existing infrastructure.

Most arctic facilities are connected with population concentrations, extraction of natural resources, or military activity. In the case of industrial or military developments, facilities typically include industrial buildings and warehouses, crew and worker quarters, embankments (roadway, airport, work pad), pipelines (both chilled and warm), and excavations of different types. Many industrial buildings must be designed to accommodate heavy equipment, increasing demands on the foundation system. In the case of human settlements, infrastructure includes public transportation systems, utility generation and distribution facilities, and buildings associated with residential or business activities. In addition to the complexity presented by the wide range in requirements of the different types of infrastructure, the problems associated with climate change are compounded by the range of environmental conditions over which human activities occur, extending from the sporadic permafrost/seasonal frost zone to the high Arctic with its cold, continuous permafrost layer.

Some of the engineering projects that are likely to be affected by climate change are as follows (see also Bush et al., 1998; Nixon, 1994).

- Northern pipelines are likely to be affected by frost heave and thaw settlement. Slope stability is also likely to be an issue in discontinuous permafrost (Nixon et al., 1990).
- The settlement of shallow pile foundations in permafrost could possibly be accelerated by temperature increases over the design life of a structure (~20 years). However, over the same period, there is very likely to be less of an effect on the deeper piles used for heavier structures (Nixon et al., 1990).
- Large tailings disposal facilities might be affected (negatively or positively) by climate change, due to the long-term effects on tailings layers. There is some chance that layers that freeze during winter deposition in northern seasonal-frost or permafrost areas would thaw out many years later, releasing excess water and contaminants into groundwater. There is some chance that

increasing temperature would significantly change the rate of thawing of such layers.

- The availability of off-road transportation routes (e.g., ice roads, snow roads) is likely to decrease owing to a reduction in the duration of the freezing season. The effect of a shorter freezing season on ice and snow roads has already been observed in Alaska and Canada (section 16.3.6).
- Climate change is likely to reduce ice-cover thickness on bodies of water and the resulting ice loading on structures such as bridge piers. However, until these effects are observed, it is unlikely that engineers will incorporate them into the design of such structures.
- The thickness of arctic sea-ice cover is also likely to change in response to climate change, and it is possible that this will affect the design of off-shore structures for ice loadings, and the design of ice roads used to access structures over land-fast ice in winter.
- Precipitation changes are very likely to alter runoff patterns, and possibly the ice–water balance in the active layer. It is very difficult to assess the potential effects of these changes on structures such as bridges, pipeline river crossings, dikes, or erosion protection structures.
- The stability of open-pit mine walls will possibly be affected where steep slopes in permafrost overburden have been exposed for long periods of time. The engineering concerns relate to increased thaw depth over time, with consequent increased pore pressures in the soil and rock, and resulting loss of strength and pit-wall stability (Szymanski et al., 2003; Bush et al., 1998).
- The cleanup and abandonment of military and industrial facilities throughout the Arctic sometimes involves storage of potentially hazardous materials in permafrost or below the permafrost table. There is some chance that permafrost degradation associated with climate change will threaten these storage facilities. AMAP (1998) provides a detailed review of arctic pollution issues.


For all types of arctic infrastructure, the key climate-related concern is changes in the thermal state of the supporting soil layers. As described in section 16.2.2.5, changes in soil temperature can induce large variations in soil strength and bearing capacity and may also cause thaw settlement or frost heave. Many facilities and structures were designed for current climatic conditions, and it is possible that appreciable warming will introduce differential settlement beneath them. The susceptibility of permafrost to environmental hazards associated with thermokarst, ground settlement, and several other destructive cryogenic processes can be crudely evaluated using the geocryological hazard index, which is the combination of the projected percentage change in active-layer thickness and the ground ice content:

$$I_s = \Delta z_{al} \bullet V_{ice} \qquad \text{Eqn. 16.2}$$

where Δz_{al} is the percentage increase in active-layer thickness, and V_{ice} is the volumetric proportion of near-surface soil occupied by ground ice. The index provides a qualitative representation of relative risk, with lower values representing lower risk and vice versa.

Future geocryological hazards were projected using several scenarios of climate change (including those from the ACIA-designated models) as input to a permafrost model that included information about existing permafrost and ground ice distributions from the IPA. Figure 16.19 presents the geocryological hazard potential with respect to engineered structures projected for 2050, calculated using the HadCM3 scenario (Anisimov and Belolutskaia, 2002; Nelson F. et al., 2002). The map shows areas projected to have low, moderate, and high susceptibility to thaw-induced settlement, as well as areas where permafrost is projected to remain stable.

A zone of high and moderate risk potential is projected to extend discontinuously around the Arctic Ocean, indicating high potential for coastal erosion. North American population centers (e.g., Barrow, Inuvik) and river terminals on the arctic coast of Russia (e.g., Salekhard, Igarka, Dudinka, and Tiksi) fall within this zone. Transportation and pipeline corridors traverse areas of high projected hazard potential in northwestern North America. The area containing the Nadym-Pur-Taz natural gas production complex and associated infrastructure in northwest Siberia also falls in the projected high-risk category. Large portions of central Siberia, particularly the Sakha Republic (Yakutia) and the Russian Far East, have moderate or high projected hazard potential. These areas include several large population centers (Yakutsk, Noril'sk, and Vorkuta), an extensive network of roads and trails, and the Trans-

Fig. 16.19. Projected geocryological hazard potential in 2050, based on output from the HadCM3 model (Anisimov and Belolutskaia, 2002; Nelson F. et al., 2002).

- High

Siberian and Baikal–Amur mainline railroads. The Bilibino nuclear power station and its grid occupy an area of projected high hazard potential in the Russian Far East. Areas of lower projected hazard potential are associated with mountainous terrain and cratons (geologically stable interior portions of continents) where bedrock is at or near the surface.

Three main design approaches are employed when using permafrost soils as foundations for structures and infrastructure (Andersland and Ladanyi, 1994):

- to maintain the existing ground thermal regime (referred to as Principle I in Russia, and the passive method in North America);
- to accept changes in the ground thermal regime caused by construction and operation, or to modify foundation materials prior to construction (referred to as Principle II in Russia, and the active method in North America); and
- to use conventional foundation methods if the soils are thaw stable.

With the first two methods, it is necessary to estimate the maximum active-layer thickness and the maximum permafrost temperature as a function of depth that the structure will be subjected to in its lifetime. The air thawing index can be used to calculate active-layer thickness and maximum permafrost temperatures as a function of depth and time of year (see section 16.2.2.2). Other approaches can also be used to calculate active-layer thickness (e.g., using a full surface energy balance).

A significant consequence of permafrost degradation is likely to be a change in the maintenance conditions of many structures, especially for those that were designed without consideration of potential climate change. Projections of the change in bearing capacity and durability of foundations as temperatures change illustrate the potential for damage as a result of climate change. The results of such calculations for Yakutsk are presented in Table 16.9.

For structures utilizing Principle I (permafrost conservation), the table illustrates that foundation failures will possibly begin when the mean annual air temperature increases by a small amount (a few tenths of a

Table 16.9. Projected decrease in the bearing capacity and durability of foundations in Yakutsk for different increases in air temperature (Khrustalev, 2000).

	Increase in mean annual air temperature (°C)				
	0	0.5	1.0	1.5	2.0
Bearing capacity of structures built using Principle I (%)	100	93	85	73	50
Foundation durability of structures built using Principle II (%)	100	68	46	42	23

degree), and extend to all foundations when the increase exceeds 1.5 °C. This indicates that there is little margin for safety in the bearing capacity related to changes in air temperature. For structures utilizing Principle II (permafrost thawing), design is based on allowable deformations. As with structures utilizing Principle I, no factor of safety is included in the design. However, foundation failures will occur a relatively long time after the temperature changes. This means that the change in temperature affects only the durability of the foundations. Table 16.9 shows that a small increase in air temperature substantially affects the stability of the building, and the safety of the foundation decreases sharply with rising temperatures.

Temperature increases can result in a significant decrease in the lifetime and potential failure of the structure (Khrustalev, 2000, 2001). Permafrost engineers, therefore, face the problem of preserving infrastructure under projected future climate conditions. The compensation method (putting new buildings into operation as existing ones are damaged and abandoned) appears to be one of the possible ways to address this problem. However, Khrustalev (2000, 2001) states that this method will be inadequate, since the required rate of new construction rises exponentially from 5% per decade in 1980–1990 to 108% per decade in 2030–2040 (assuming a linear increase in mean annual temperature of 0.075 °C/yr) .

Various methods have been suggested to address temperature-related foundation problems. Techniques to reduce warming and thawing, such as heat pumps, convection embankments, thermosyphons, winter-ventilated ducts, and passive cooling systems, are already common practice in North America, Scandinavia, and Russia (Andersland and Ladanyi, 1994; Couture et al., 2003; Goering and Kumar, 1996; Instanes, B., 2000; Khrustalev and Nikiforov, 1990; Smith S. et al., 2001).

16.3.1. Ultraviolet radiation and construction materials

Ultraviolet (UV) radiation adversely affects many materials used in construction and other outdoor applications. Exposure to UV radiation can alter the mechanical properties of synthetic polymers used in paint and plastics, and natural polymers present in wood. Increased exposure to UV radiation due to stratospheric ozone depletion is therefore likely to decrease the useful life of these materials (Andrady et al., 1998).

The impact of UV radiation on infrastructure in the Arctic is influenced by two compounding factors: the high surface reflectivity of snow or ice and long hours of sunlight. Both factors have strong seasonal components, generally resulting in increased UV radiation levels in the late spring. While the level of UV radiation incident on a horizontal surface (e.g., a flat roof) may be considerably lower in the Arctic than at mid-latitudes, the level

of UV radiation incident on a vertical surface (e.g., a south-facing wall) may be higher than that on a horizontal surface at some times of the year, when reflection from snow augments the direct UV radiation incident on the surface. Materials degradation is often related to the total accumulated UV radiation exposure.

Long days during the arctic summer can result in large daily doses of UV radiation, even when noon levels remain moderate. If UV radiation levels increase as a result of ozone depletion or changes in cloud cover, the impacts on materials are likely to include earlier degradation and significant discoloration.

For natural polymers found in wood, exposure to UV radiation can lead to a decrease in the useful lifetime of the product. Even small doses of UV radiation may darken wood surfaces. Other effects of increased exposure to UV radiation on wood are less certain. The damage to finished wood products is limited primarily by protective surface coatings, but increased UV radiation levels will possibly lead to increased costs for more frequent painting or other maintenance.

The construction industry is increasingly turning to synthetic polymers for use in building materials. In the United States and Western Europe, the building sector uses 20 to 30% of the annual production of plastics (Mader, 1992). Plastics and other synthetic polymer products are used for a number of applications, including irrigation, water distribution and storage, and in fishing nets and agricultural films.

During the manufacture of virtually all polymer products, impurities can be introduced that make the end product susceptible to photodegradation by UV radiation. Although stabilizers may be added to retard photodegradation effects, their inclusion can substantially increase the cost of the final product. Unfortunately, much of the research on UV-induced degradation has been conducted on pure polymer resins, leading to problems in extrapolating the findings to processed products of the same polymer.

The effects of UV radiation on materials are closely tied to other environmental factors, including ambient temperatures. Polar regions have experienced the greatest ozone depletion and therefore the greatest potential increases in UV-B radiation levels. However, the cooler temperatures in these locations can help prevent rapid degradation of materials. Materials have different sensitivities that can depend on wavelength and dose. Some materials contain stabilizers designed to mitigate degradation, but the efficacy of those stabilizers under spectrally altered (e.g., higher than normal UV) conditions is not always known (Andrady, 1997).

UV-induced polymer deterioration has been widely observed. Polyvinyl chloride tends to undergo discoloration or yellowing, and to lose impact strength. This loss of impact strength can eventually lead to

cracking and other irreversible damage. Another polymer, polycarbonate, undergoes a rearrangement reaction when exposed to UV-B or UV-C radiation. When irradiated at longer wavelengths, including visible wavelengths, polycarbonates undergo oxidative reactions that result in yellowing (Factor et al., 1987).

Polystyrene, used as expanded foam in both building and packaging applications, also undergoes light-induced color changes. In polyethylene and polypropylene, which are used extensively in agricultural mulch films, greenhouse films, plastic pipes, and outdoor furniture, the loss of tensile properties and strength is a particular concern (Hamid and Pritchard, 1991; Hamid et al., 1995).

The cost of more frequent replacement of woods and polymers is likely to be higher in the Arctic than at lower latitudes because of the increased cost of shipping and placement. Environmental stresses in the Arctic, including high winds and repeated freezing and thawing, will possibly exacerbate minor materials problems that develop as a result of UV radiation damage.

16.3.2. Buildings

Several foundation systems are currently in use for industrial, commercial, and residential structures situated in the Arctic and subarctic. When building sites are underlain by permafrost, the foundation system must ensure that any warmth emanating from the structure does not induce thawing of the permafrost layer. For many structures, this is accomplished by elevating the building above the ground surface on a pile or adjustable foundation system. The resulting air space ensures that heat from the structure will not induce permafrost warming. Thousands of structures ranging from single-family residences to large living quarters and apartment blocks are currently supported on pile foundations, including many residential structures in the permafrost zones of Alaska, Canada, and Scandinavia, and many apartment buildings in Siberia. In most of these areas, existing structures are performing well, and there has been little evidence that climate change is inducing failures. However, as noted in section 16.3.8 many Siberian buildings are experiencing significant rates of structural failure that may be connected to increasing temperatures.

The bearing capacity of piles embedded in permafrost depends on the type of frozen soil (clay, silt, or sand), its temperature, and the length of pile embedment in the permafrost layer. A safe pile design is usually based on the calculated maximum temperatures of the frozen soil along the embedded pile length, determined from data on the mean annual temperature of the site and the seasonal temperature variation. Pile foundations are particularly sensitive to permafrost temperatures because of the large increase in creep rates as temperatures approach 0 °C (see section 16.2.2.5). For this reason, extra cooling measures, such as the use of thermopiles (thermosyphon-cooled pilings), are some-

times taken in the warmer discontinuous permafrost zone in order to lower temperatures and ensure a stable permafrost–piling bond.

An increase in ground temperature along an existing pile is very likely to reduce its bearing capacity or increase the rate of its settlement for two reasons: an increase in the active-layer thickness will reduce the effective embedment length of the pile; and increased temperature will reduce the strength of the frozen soil. As a result, if soil warming occurs, an existing structure founded on piles will experience an increasing settlement rate that is likely to lead to uneven settlement and damage to the structure.

The design of all future structures founded on piles embedded in permafrost soils should take into account projected future temperature increases. Depending on the estimated useful lifetime of the structure, the pile design should preferably be based on projected temperature conditions at the end of its lifetime. For any particular pile type, unless bearing on rock, this will result in longer pile length and increased cost.

Very light buildings in permafrost areas are often established directly on the ground surface and supported by a system of adjustable mechanical jacks providing a sufficient crawl space below the heated and insulated floor of the building and the ground surface. Although such buildings will not produce thaw settlement of underlying permafrost, they are likely to be subject to the effects of regional thaw settlement due to rising temperatures and the resulting increase in active-layer thickness. Although settlement in these types of buildings can be adjusted by the jacking system, the differential settlement of water supply and sewage evacuation pipes attached to the building must also be addressed.

Depending on local meteorological conditions, the foundation soils of buildings constructed on elevated foundation systems (either pile or adjustable supports) are likely to be less prone to temperature increases as climate change occurs. This is due to the combined influence of shielding the surface from solar radiative input (due to shading by the structure) and elimination of snow cover at the surface beneath the building, both of which have a significant cooling effect on ground-surface temperatures.

For industrial and equipment buildings that must support large floor loads, pile foundations are sometimes too costly. These buildings often have a slab-on-grade foundation with insulation installed beneath the floor to help protect the underlying permafrost. In addition to the insulation, some sort of cooling system under the slab is required to remove heat from beneath the structure. Both active and passive refrigeration systems have been employed for this purpose, but passive systems are generally preferred due to their lower operational and maintenance costs. Passive systems are based on either thermosyphon or air-duct cooling systems, and utilize

low ambient temperatures during winter to refreeze a buffer layer of non-frost-susceptible material beneath the building. The buffer layer typically consists of a pad of granular material that is placed before building construction and sized to contain the seasonal thaw that develops beneath the building during summer months when the passive cooling system is inactive.

Increasing air temperature is very likely to have a detrimental effect on the operation of these foundation systems for two reasons. Higher air temperatures are likely to lengthen the thaw season and place increased requirements on the thickness of the buffer layer and/or the insulation system, and reduced air freezing indices (section 16.2.2.4) are very likely to decrease the capacity of the passive cooling system to refreeze the buffer layer material during winter.

As a result, existing buildings built on slabs are likely to experience an increasing failure rate as air temperatures rise and produce either significantly longer thaw seasons or a reduced freezing index. Future designs for such buildings will need to take into account temperature increases projected for the lifetime of the structure. This is very likely to increase costs due to the need for additional buffer layer material and higher cooling capacities.

16.3.3. Road and railway embankments and work pads

Transportation routes are likely to be particularly susceptible to destructive frost action under conditions of changing climate. Garagulya et al. (1997) developed a map showing areas with various probabilities of natural hazards. This map indicated that the regions of highest susceptibility to frost heave and thaw settlement are located along the Arctic Circle.

The design of road and railway embankments in the Arctic is complicated by the presence of underlying permafrost, due to the possibility of thaw settlement and significant permanent embankment deformation if thermal disturbance occurs. The situation is exacerbated by complex thermal interactions between the embankment and the surrounding environment. Embankment construction often produces a significant alteration of the surface microclimate that results in an increase in mean annual surface temperature of several degrees as compared to natural conditions. Precise temperature increases are a complex function of embankment surface conditions, maintenance operations (e.g., snow clearing patterns), and the pre-existing natural vegetation, and are sometimes difficult to project.

In the continuous permafrost zone, where the permafrost layer and surface conditions are generally colder, surface warming due to embankment construction can usually be accommodated using well-established design practices. In this case, the embankment thickness is adjusted to ensure that seasonal thawing is contained

within the embankment itself, thus avoiding thawing of the underlying permafrost. The required embankment thickness is sensitive to climatic conditions, tending to increase significantly with warmer conditions.

In the discontinuous permafrost zone, permafrost and ground-surface temperatures are warmer, often within a few degrees of the melting point. In this zone, it is more difficult to accommodate surface warming due to embankment construction since the resulting mean surface temperatures are often above the melting point. In this case, long-term thaw of the permafrost layer can be expected and cost-effective design strategies are currently unavailable. In a limited number of cases, techniques such as thermosyphon, air duct, or convection cooling systems have been used to mitigate these problems (Andersland and Ladanyi, 1994; Goering, 2003; Goering and Kumar, 1996; Instanes, B., 2000; Phukan, 1985), however, the expense associated with these systems severely limits their utility. In practice, even under current climatic conditions, many road and railway embankments located in regions of warm discontinuous permafrost experience high failure rates and resulting high maintenance costs. Typical problems include differential thaw settlement and shoulder failure due to thawing permafrost, resulting in an uneven, cracked embankment surface (Fig. 16.20). The timescales associated with permafrost thaw beneath embankments are of the order of the embankment lifetime (20 to 30 years), thus necessitating a continuous maintenance program.

Increasing temperatures are very likely to affect embankment performance in both the continuous and discontinuous permafrost zones and should be considered in the design of future projects. In the discontinuous permafrost zone, the problems associated with permafrost thaw described above are very likely to increase as increasing air temperature adds to the warming influence of embankment construction. This is very likely to result in increased failure rates and higher maintenance costs. As climate change reduces permafrost extent in the southern discontinu-

ous permafrost zone, some reduction in these embankment problems is possible, although the timescales for projected warming and thaw are much longer than typical project lifetimes.

In the continuous permafrost zone, increasing temperatures are likely to have negative impacts on embankment performance for two reasons:

- increased surface temperatures will necessitate greater embankment thicknesses in order to contain the seasonal thaw depth. This is very likely to have a large impact on project costs due to the difficulty and expense associated with obtaining appropriate granular material for embankment construction; and
- as air and surface temperatures increase, a design regime shift will possibly occur in association with the northward movement of the boundary between the discontinuous and continuous permafrost zones. It is possible that increasing embankment thickness alone will no longer be sufficient to protect underlying permafrost and greater failure rates will occur, similar to those seen in the discontinuous permafrost zone.

As a result, it is likely that existing road, rail, or airport embankments will experience increasing failure rates both in the continuous and discontinuous permafrost zones. Future embankment designs should incorporate the effects of projected temperature increases over the lifetime of the project, which is likely to increase construction costs.

16.3.4. Pipelines

Many of the earth's remaining oil and gas reserves are located in regions of the Arctic far from population centers. These areas include the North Slope of Alaska, the Canadian Arctic, northwestern Russia, and Siberia. The limited exploitation of these resources to date has relied primarily on pipeline systems to transport products to market. Future expansion of these pipeline networks is likely given the increasing demand for fossil fuels worldwide. Examples include the large gas pipeline projects currently under consideration to connect natural gas reserves in the Alaskan and western Canadian Arctic to southern Canada and the continental United States. Many of the current and anticipated pipeline routes cross extensive areas of continuous and discontinuous permafrost and require special design considerations.

Oil and gas pipelines differ in their interactions with the surrounding environment because of variations in operating temperature. Transmission of oil through pipelines usually takes place at high temperatures because of high oil-well production temperatures and reduced pumping losses. Conversely, natural gas transmission through pipelines often takes place at temperatures below freezing in order to increase gas density

Fig. 16.20. Typical embankment cracking and differential thaw settlement in the discontinuous permafrost zone of Interior Alaska (Photo: Larry Hinzman, University of Alaska, Fairbanks).

and throughput. High- or low-temperature pipelines present different challenges to designers and will react in different ways to increased air temperatures.

Gas and oil pipelines are normally constructed below the ground surface, as this reduces construction costs and provides other benefits. In the case of warm-oil pipelines, this becomes problematic in areas where permafrost is encountered. The desire to keep the oil warm to limit viscosity and pumping costs is in direct conflict with the requirement to maintain the frozen state of the surrounding soil. If the pipeline is buried, no practical amount of insulation will prevent the warm oil from thawing surrounding permafrost, thus resulting in loss of strength, thaw settlement, and probable line failure. As a result, designers have relied on one of two methods to avoid permafrost degradation:

- an elevated oil pipeline that is supported above the ground surface on some sort of pile foundation, thus limiting the possibility of permafrost thaw; or
- a more conventional buried pipeline design, with the oil chilled to near-permafrost temperatures (typically below 0 °C for a large part of the year).

A major shortcoming of both methods, particularly with regard to potential climate change, is their reliance on the permafrost layer for structural support. In the first case, the piles are embedded in the permafrost, as for a building foundation, and the adfreeze bond between the pile and the permafrost supports the load. In the second case, the integrity of the pipe trench and support of the pipeline are dependent on the structural integrity of the underlying permafrost. Both methods result in increased cost; the first due to the large expense of constructing an elevated line, and the second due to the high pumping costs associated with moving chilled oil and related problems with potential wax formation in the line.

The best-known example of an existing elevated arctic oil pipeline is the Trans Alaska Pipeline System (TAPS), which stretches 1280 km from Prudhoe Bay to the ice-free port of Valdez in southern Alaska. This pipeline is elevated for just over half of its length in order to avoid potential permafrost problems. The northern sections, where permafrost temperatures are cold (lower than approximately -5 °C), utilize non-refrigerated pile supports and a work-pad embankment designed to protect underlying permafrost. In the more southerly sections, where warmer discontinuous permafrost is encountered, the piles utilize a passive refrigeration system consisting of pairs of thermosyphons installed in each piling. More than 120 000 thermosyphons are used (Sorensen et al., 2003). The thermosyphons are designed to ensure that any excess heat transported downward from the pipeline or entering the ground surface due to construction disturbance will not cause thawing of the permafrost where the piles are embedded.

Owing to the extensive use of pile supports, elevated oil pipelines are sensitive to increasing air and soil temperatures, as are building-support pilings. Increased soil temperatures are very likely to reduce the bearing capacity of these systems because of the reduction in the strength of the adfreeze bond between the frozen soil and the pile. In addition, increased air temperatures are very likely to result in a greater active-layer depth, which will reduce the effective embedment length of the pile in the frozen zone. Some of these effects can be countered by the use of refrigerated piles, as in the case of TAPS; however, increased air temperatures are also very likely to reduce the ability of these systems to provide adequate cooling. It is also possible that the pipeline right-of-way and work-pad embankment will begin to experience increased problems with thaw settlement due to the combination of surface disturbance and increasing air temperature. These factors should be considered during the design stage of future projects.

The Norman Wells Pipeline, which runs 896 km through the western Canadian Arctic from Norman Wells, Northwest Territories, to Zama City, Alberta, is an example of a chilled pipeline that is buried in permafrost terrain. The oil is chilled by a refrigeration system before it enters the line at Norman Wells, and operates at near-ambient permafrost temperatures. Even though the oil is chilled to minimize permafrost disturbance, the designers anticipated a significant amount of thaw settlement and/or frost heave along the route (Nixon et al., 1984). To resist the anticipated loading due to thaw strain or frost heave, a relatively high-strength system consisting of a small-diameter thick-wall pipe was used. Two major design/performance issues were identified as the most significant for this project: adequate thermal conditions must be maintained such that design loads due to thaw settlement or frost heave are not exceeded; and permafrost thaw within the pipeline trench and right-of-way must be limited in order to avoid slope instability (and potential landslides) in areas of sloped terrain.

Variations in line operating conditions have resulted in significant movement of the pipe due to thaw settlement and frost heave. In some places, thaw settlement near the pipeline trench has exceeded the design projections of 1 m (Burgess and Smith, 2003), and increases in thaw depth have reduced the factor of safety for slope stability (Oswell et al., 1998).

Many of the difficult operational issues identified above for buried ambient-temperature pipelines result from the thermal interaction between the pipe and the surrounding ground. These difficulties are likely to be exacerbated if air temperatures also change over time. Increased air temperatures are likely to aggravate problems with thaw settlement along the right-of-way and decrease slope stability. To some extent, it may be possible to reduce the severity of these problems by decreasing the operational temperatures of the pipeline,

however this is not desirable because of the high pumping cost and wax formation issues mentioned previously. New projects should take projected temperature increases into account during the design stage and may have to increase measures designed to prevent slope instability and settlement associated with permafrost thaw.

Unlike oil pipelines, gas pipelines benefit from low-temperature operation and are often operated at temperatures significantly below the freezing point. When these pipelines are buried in continuous permafrost, they aid the maintenance of the permafrost layer and design is straightforward. On the other hand, where chilled buried pipelines must traverse zones of discontinuous permafrost, problems can be expected. In this case, the chilled pipeline will cause freezing of the thawed soil present along the route, some of which may be susceptible to frost. The resulting frost-heave loads on the pipe can be large and must be accounted for carefully. Previous studies have suggested that line operation temperatures should be kept only moderately below freezing in these areas in order to minimize frost-heave problems while, at the same time, avoiding thaw settlement in the permafrost portions of the route (Jahns and Heuer, 1983). Increased air temperatures will possibly expand the problematic portion of these pipeline routes as the boundary between continuous and discontinuous permafrost moves northward. However, the ability to control pipeline operating temperatures may help to adapt to changing climatic conditions.

16.3.5. Water-retaining structures

Water-retaining embankments in permafrost are discussed in detail by Andersland and Ladanyi (1994), and are generally one of two types: unfrozen embankments or frozen embankments. With unfrozen embankments it is assumed that the permafrost foundation will thaw during the lifetime of the structure. This type is limited to sites with thaw-stable foundation materials or bedrock, or cases where the water is retained for a short period of time. With frozen embankments it is assumed that the permafrost foundation will remain frozen during the lifetime of the structure. This type is suitable for continuous permafrost areas and other areas where the foundation materials are thaw-unstable.

The embankment design for a particular site must combine the principles of soil mechanics for unfrozen soils and the mechanical behavior of permafrost. The design should always include thermal and stability considerations, and for permanent structures, potential climate change should be taken into account. Sayles (1984, 1987) and Holubec et al. (2003) have summarized the factors that are relevant to embankment design.

Problems associated with water-retaining dams include seepage, frost heave (in areas of seasonal frost), settlement, slope stability, slope protection, and construction methods. Increased air temperatures are not likely to affect unfrozen embankments because the perma-

frost foundation is thaw stable. Frozen embankments usually require supplementary artificial freezing to ensure that the foundation and embankment remain frozen (Andersland and Ladanyi, 1994). Increased air temperatures are likely to increase the construction and operational costs of frozen embankments due to the increased energy demand required to keep the embankment frozen.

16.3.6. Off-road transportation routes

In recent years, temporary winter transportation routes have played an increasingly important role for community supply and industrial development in the permafrost zones of North America. These transportation corridors consist of ice roads that traverse frozen lakes, rivers, and tundra. In some cases, ice roads are constructed for one-time industrial mobilizations, such as oil and gas exploration activities. In other cases, permanent ice-road corridors have been established and are reopened each winter season. Winter ice roads offer important advantages that include low cost and minimal impact to the environment. Oil and gas exploration can be conducted from these road structures with very minimal ecological effects, and costs associated with construction and eventual removal of more permanent gravel roads or work pads can be avoided.

Winter ice-road construction is affected by a number of climatic factors, including air temperature, accumulated air freezing index, and snowfall. These roads depend on the structural integrity of the underlying frozen base material and, thus, a significant period of freezing temperature must occur each autumn before ice-road construction can begin. For water crossings, the critical factor influencing the start of the winter-road season is the rate and amount of ice formation. Ice thickness must reach critical minimum values before vehicles and freight can be supported safely. For tundra areas (particularly where temporary transportation routes are needed), a critical issue is protection of the existing vegetative cover. In this case, the active layer must be frozen to a depth that is sufficient to support anticipated loads and avoid damage to vegetation. Once a sufficient frozen layer has been established, the surface is covered with snow and water is applied and allowed to freeze in place. The result is a durable driving surface that can support significant loads without harming the underlying vegetation.

In North America, winter-road use and construction is regulated to avoid environmental damage to the tundra. Various inspection techniques are used to ensure adequate freezing before the winter-road season is opened. One technique employs a penetrometer that is pushed into the frozen active layer to measure the strength and thickness of the frozen zone. Based on these measurements, regulatory agencies make decisions regarding opening and closing dates for winter-road travel.

Climatic conditions play a strong role in determining the opening and closing dates for winter-road travel, although inspection techniques and load requirements, among other factors, are also important. Increased air temperature and reductions in the annual air freezing index are very likely to have a negative impact on the duration of the winter-road season. This will possibly become particularly problematic for oil and gas exploration because of the time needed at the beginning and end of the ice-road season for mobilization and demobilization.

Hinzman et al. (in press) present historic data for the opening and closing dates for tundra travel on the North Slope of Alaska that show a substantial reduction in the duration of the winter-road season (from over 200 days in the early 1970s to just over 100 days in 2002). The rate of reduction has been fairly consistent over the intervening years and is due primarily to delayed opening dates (from early November in the 1970s to late January in the 2000s), although closing dates have also been occurring earlier in the spring. Reductions in the duration of the winter-road season have also occurred in the Canadian Arctic, however the reductions are much smaller than those observed in Alaska, and in some cases the season length has increased.

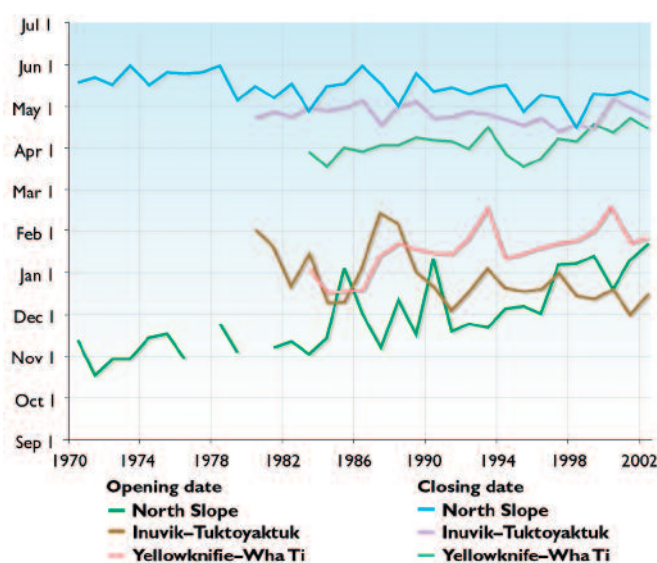
Fig. 16.21 shows historic data for opening and closing dates of winter roads on the North Slope of Alaska and in Canada's Northwest Territories. The data for the North Slope are for temporary winter roads used primarily for oil and gas exploration, whereas the data for the Northwest Territories are for the winter roads between Inuvik and Tuktoyaktuk (187 km) and between the Yellowknife Highway and Wha Ti (103 km). The figure illustrates the reduction in season length for the North Slope of Alaska, and a trend of later opening


Fig. 16.21. Opening and closing dates for winter roads on the North Slope of Alaska and the Inuvik–Tuktoyaktuk and Yellowknife Highway–Wha Ti winter roads in western Canada (North Slope data after Hinzman et al., in press; Canadian data from the Government of the Northwest Territories, Department of Transportation, www.hwy.dot.gov.nt.ca/highways/, 2003).

dates for the Wha Ti road. Data for the Inuvik-Tuktoyaktuk road, however, indicate an increased season length.

The observed trend in Alaska shows that climate change is likely to lead to decreased availability of off-road transportation routes (ice roads, snow roads, etc.) due to reduced duration of the freezing season.

16.3.7. Offshore transportation routes

The global economy of the 21st century will need the natural resources of the Arctic and subarctic. Air transport remains unprofitable for mineral payloads and attention to arctic shipping is growing as a result. Road, rail, and pipeline routes are complicated in the far north by tectonically active glacier-contorted landscapes, low-lying frozen ground, and fragile ecosystems. Shorter routes from resource to tidewater minimize terrestrial complications only if a port can be built at the coast. New ice-breaking ship designs are continually improving the efficiency of arctic shipping. Growing evidence of climate change indicates that ice-free navigation seasons will probably be extended and thinner sea ice will probably reduce constraints on winter ship transits (section 16.2.5). Additional northern port capacity is critical to the success of arctic shipping strategies associated with northern resource development and potential climate change. Difficulties related to freezing temperatures, snow accumulation, and extended darkness compound the challenges of geotechnical, structural, architectural, mechanical, electrical, transportation, and coastal engineering in designing and operating sea and river ports.

The International Northern Sea Route Programme was a six-year (June 1993 – March 1999) international research program designed to create an extensive knowledge base about the ice-infested shipping lanes along the coast of the Russian Arctic, from Novaya Zemlya in the west to the Bering Strait in the east. This route was previously named the Northeast Passage, but is now more often known by its Russian name – the Northern Sea Route.

Projected reductions in sea-ice extent are likely to improve access along the Northern Sea Route and the Northwest Passage. Projected longer periods of open water are likely to foster greater access to all coastal seas around the Arctic Basin. While voyages across the Arctic Ocean (over the pole) will possibly become feasible this century, longer navigation seasons along the arctic coasts are more likely. Development of the offshore continental shelves and greater use of coastal shipping routes will possibly have significant social, political, and economic consequences for all residents of arctic coastal areas.

Output from the five ACIA-designated climate models was used to project the length of the navigation season along the Northern Sea Route based on the amount of

sea ice present. Figure 16.22 shows the five-model mean for three conditions: 25, 50, and 75% open water across the Northern Sea Route. If ships sailing along the Northern Sea Route are designed for and capable of navigating in waters with 25% open water (75% sea-ice cover), the projected length of the navigation season is considerably longer than that for ships that are minimally ice-capable and can only navigate in 75% open water (25% sea-ice cover).

There are few days when, even at mid-century, the Northern Sea Route is covered by 75% open water (25% sea-ice cover). When days on which navigation is possible are defined by a higher ice-cover percentage, the length of the navigation season increases. In 2050, Fig. 16.22 shows a projected navigation season length of 125 days under conditions of 25% open water (75% sea-ice cover); conditions very favorable for the transit of ice-strengthened cargo ships. However, the ACIA-designated model projections provide no information on sea-ice thickness, a critical factor for ice navigation. Section 16.2.5.2 provides additional projections of future sea-ice conditions.

With increased marine access to arctic coastal seas, national and regional governments are likely to be called upon for increased services such as icebreaking assistance, improved sea-ice charts and forecasting, enhanced emergency response capabilities for sea-ice conditions, and greatly improved oil–ice cleanup capabilities. The sea ice, although thinning and decreasing in extent, will possibly become more mobile and dynamic in many coastal regions where fast ice was previously the norm. Competing marine users in newly open or partially ice-covered areas in the Arctic are likely to require increased enforcement presence and regulatory oversight.

A continued decrease in arctic sea-ice extent this century is very likely to increase seasonal and year-round

Fig. 16.22. Length of the navigation season along the Northern Sea Route projected by the ACIA-designated climate models (five-model mean).

access for arctic marine transportation and offshore development. New and revised national and international regulations, focusing on marine safety and marine environmental protection, are likely to be required as a result of these trends. Another probable outcome of changing marine access will be an increase in potential conflicts between competing users of arctic waterways and coastal seas.

Based on the scenarios presented in this section and in section 16.2.5.2, a longer navigation season along the arctic coast is very likely and trans-arctic (polar) shipping is possible within the next 100 years.

16.3.8. Damage to infrastructure

Instanes A. (2003) pointed out that for structures on permafrost it is often difficult to differentiate between the effect of temperature increases and other factors that may affect a structure on permafrost. For example: the site conditions are different from the assumed design site conditions; the design of the structure did not take into account appropriate load conditions, active-layer thickness, and permafrost temperature; the contractor did not carry out construction according to the design; the maintenance program was not carried out according to plan; and/or the structure is not being used according to design assumptions. In addition, it is very difficult to find cost-effective engineering solutions for foundations or structures on warm (T >-1 °C), discontinuous permafrost.

Kronik (2001) summarized reports on damage to infrastructure in Russian permafrost areas from the 1980s to 2000. The reported deformations of foundations and structures were caused not only by climate change, but also by other factors such as those listed above, particularly the low quality and inadequate maintenance of structures. Unfortunately, it is difficult to distinguish between these factors. The analysis of deformation causes performed by Kronik (2001) for industrial and civil complexes showed that 22, 33, and 45% of the deformations were due to mistakes by designers, contractors, and maintenance services, respectively (see also Panova, 2003). Out of 376 buildings surveyed, 183 (48.4%) did not meet building code requirements in 1992, including 21 buildings (8.5%) that were unfit for use (Kronik, 2001). The percentage of dangerous buildings in large villages and cities in 1992 ranged from 22% in the village of Tiksi to 80% in the city of Vorkuta, including 55% in Magadan, 60% in Chita, 35% in Dudinka, 10% in Noril'sk, 50% in Pevek, 50% in Amderma, and 35% in Dikson.

The condition of land transportation routes in Russia is not much better. In the early 1990s, 10 to 16% of the subgrade in the permafrost areas of the Baikal–Amur railroad line was deformed because of permafrost thawing; this increased to 46% in 1998. The majority of runways in Norilsk, Yakutsk, Magadan, and other cities may be closed for shorter or longer periods due to lack
Fig. 16.23. Annual demand for heating energy (Anisimov, 1999).

of maintenance. The main gas and oil transmission lines in the permafrost region have also suffered damage related to permafrost thawing: 16 breaks were recorded on the Messoyakha–Noril'sk pipeline in 2000.

16.3.9. Energy consumption for heating

A reduction in the demand for heating energy is a potential positive effect of climate change in the Arctic and subarctic. The air-temperature threshold that defines the beginning of the cold period, when additional heating of living facilities, businesses, and industrial buildings is necessary, varies within and between countries. In North America and Western Europe, most civil buildings, private houses, apartment complexes, and even most buildings in large cities have local heating systems. In the United States the temperature threshold for heating is defined as 65 ºF (17.8 ºC), but because the local systems are very flexible and can be manipulated individually, evaluation of energy consumption is complex.

In Eastern Europe and Russia, most urban buildings have centralized heating systems. Under standard con-

ditions, such systems operate when the mean daily air temperature falls below 8 ºC (47 ºF). Because of the large thermal inertia of these centralized heating systems, comfortable indoor temperatures (e.g., 18 ºC) are usually maintained throughout the winter.

Figure 16.23 shows the annual demand for heating energy (in 1000 ºC-days) when building heating is required (mean daily air temperature below 8 ºC) calculated for current climatic conditions. Annual heating degree-day totals characterize the demand for heating over the entire cold period. Daily heating degree-days are calculated by subtracting the mean daily temperature from the 8 ºC threshold (e.g., a day with a mean daily temperature of 5 ºC would result in three heating degree-days); days with a mean temperature at or above 8 ºC result in zero heating degree-days.

Anisimov (1999) used the GFDL, ECHAM-1 (Max-Planck Institute for Meteorology), and HadCM transient climate scenarios for 2050 to calculate the reduction in the duration of the heating period and changes in the number of heating degree-days relative to 1999. Projected reductions in the number of heating degree-days (Fig. 16.24) can be used as a metric for the reduction in heating energy consumption. Figure 16.25 shows the percentage reduction in the duration of the heating period between 1999 and 2050; this decrease is projected to vary from a few weeks to more than a month, depending on the regional effects of climate change.

The energy savings from decreased demand for heating in northern regions are likely to be offset by increases in the temperature and duration of the warm period, leading to greater use of air conditioning.

16.3.10. Natural resources

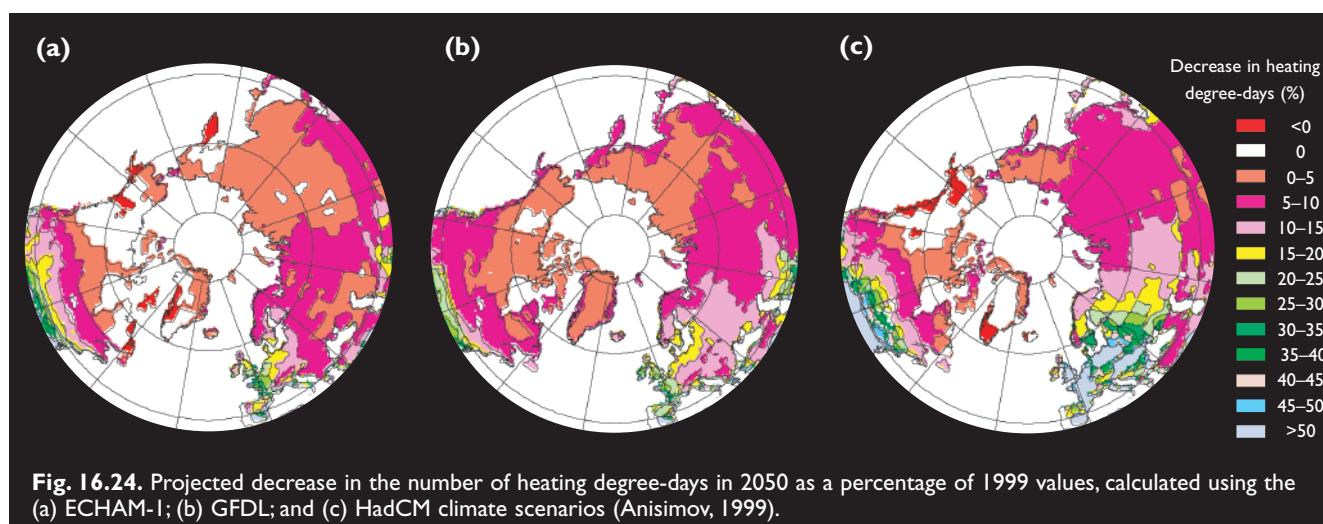
The Arctic has large oil and natural gas reserves. Most are located in Russia: oil in the Pechora Basin, natural gas in the Lower Ob Basin, and other potential oil and gas fields along the Siberian coast. Canadian oil and gas fields are concentrated in two main basins in


Fig. 16.24. Projected decrease in the number of heating degree-days in 2050 as a percentage of 1999 values, calculated using the (a) ECHAM-1; (b) GFDL; and (c) HadCM climate scenarios (Anisimov, 1999).

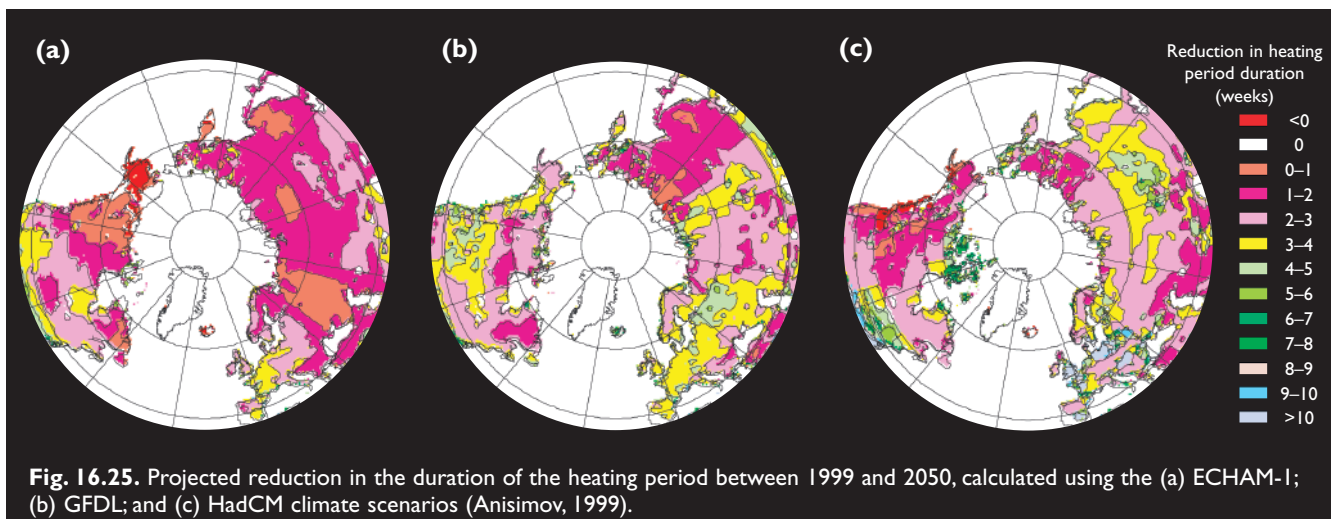
the Mackenzie Delta–Beaufort Sea region and in the high Arctic. Prudhoe Bay (Alaska) is the largest oil field in North America, and other fields have been discovered or are likely to be present along the Beaufort Sea coast. Oil and gas fields also exist in other arctic waters, for example, the Barents Sea and off the west coast of Greenland. The Arctic is an important supplier of oil and gas to the global market, and it is possible that climate change will have both positive and negative financial impacts on the exploration, production, and transportation activities of this industry.

Climate change impacts on oil and gas development have so far been minor, but are likely to result in both financial costs and benefits in the future. For example, offshore oil exploration and production is likely to benefit from less extensive and thinner sea ice because of cost reductions in the construction of platforms that must withstand ice forces. Conversely, ice roads, now used widely for access to offshore activities and facilities, are likely to be useable for shorter periods and less safe than at present. The thawing of permafrost, on which buildings, pipelines, airfields, and coastal installations supporting oil development are located, is very likely to adversely affect these structures and the cost of maintaining them (Parker, 1998; Weller and Lange, 1999; Weller et al., 1999).


The Arctic holds large stores of minerals, ranging from gemstones to fertilizers. Russia extracts the largest quantities, including nickel, copper, platinum, apatite, tin, diamonds, and gold, mostly on the Kola Peninsula but also in Siberia. Canadian mines in the Yukon and Northwest Territories supply lead, zinc, copper, and gold. Gold mining continues in Alaska, along with extraction of lead and zinc deposits from the Red Dog Mine, which contains two-thirds of US zinc resources. Coal mining also occurs in several areas of the Arctic. Mining activities in the Arctic are an important contributor of raw materials to the global economy and are likely to benefit from improved transportation conditions to bring products to market, due to a longer ice-free shipping season.

The coal and mineral extraction industries in the Arctic are important contributors to national economies, and the actual extraction process is not likely to be much affected by climate change. However, climate change will possibly affect the transportation of coal and minerals. Mines that export their products using marine transport are likely to experience savings due to reduced sea-ice extent and a longer shipping season. Conversely, mining facilities with roads on permafrost are likely to experience higher maintenance costs as the permafrost thaws (Parker, 1998; Weller and Lange, 1999; Weller et al., 1999).

Any expansion of oil and gas activities and mining is likely to require expansion of air, marine, and land transportation systems. The benefits of a longer shipping season in the Arctic, with the possibility of easy transit through the Northern Sea Route and Northwest Passage for at least part of the year, are likely to be significant. Other benefits are likely to include deeper drafts in harbors and channels as sea level rises, a reduced need for ice strengthening of ship hulls and offshore oil and gas platforms, and a reduced need for ice-breaker support. Conversely, coping with greater wave heights, and possible flooding and erosion threats to coastal facilities, is likely to result in increased costs.

16.4. Engineering design for a changing climate

Climate change is likely to affect infrastructure in different ways, as has been described in previous sections of this chapter. Some infrastructure may be relatively insensitive to climate change or easily adaptable to changing conditions. In other cases, a large sensitivity may exist and/or the consequences of any failure may be high (Esch, 1993; Ladanyi et al., 1996, Khrustalev, 2001, 2000). For infrastructure in the first category, a detailed analysis of the potential impacts of climate change may not be important, particularly given the high level of uncertainty associated with local climate trends that will affect individual projects. Conversely, for projects where high sensitivity or large consequences are possible, a detailed analysis may be warranted.

Fig. 16.25. Projected reduction in the duration of the heating period between 1999 and 2050, calculated using the (a) ECHAM-1; (b) GFDL; and (c) HadCM climate scenarios (Anisimov, 1999).

16.4.1. Risk–based evaluation of potential climate change impacts

Bush et al. (1998) presented a methodology for considering the impact of projected climate change within the framework of the engineering design process. They also explained how the same methodology can be utilized to identify and prioritize concerns about existing facilities with respect to climate change impacts. The method involves a multi-step approach that first assesses the sensitivity of a given project to climate change and then the consequences of any potential failures. The relationship between sensitivity and consequences defines the risk that climate change poses to the project. Finally, the degree of sensitivity and the severity of the consequences are used to determine what level of climate-change impact analysis should be carried out for a given project.

The sensitivity of a particular infrastructure project to climate change is determined by a number of factors, including the initial soil and permafrost temperatures, the temperature dependence of the material properties, the project lifetime, and the existing over-design or safety margin that might be included in the design for other reasons. Bush et al. (1998) included a procedure for categorizing these effects and determining the climate sensitivity of a project using a scale of high, medium, or low.

Any analysis of the consequences of failure begins with a determination of all relevant failure scenarios. These scenarios are then evaluated qualitatively using a scale of catastrophic, major, minor, or negligible, considering not only potential physical damage to the infrastructure but also socioeconomic or cultural impacts.

The final step in the screening process involves the determination of the level of climate-change impact analysis required at the design stage. Bush et al. (1998) included a table that suggests a level of analysis as a function of the degree of risk indicated by the project sensitivity and failure consequences. Level A requires a detailed quantitative analysis relying on numerical geotechnical models with refined input parameters, independent expert review, and a field-monitoring program with periodic evaluation of performance. Level B requires more limited quantitative analysis and also suggests a field-monitoring program. Level C suggests the use of qualitative analysis based on professional judgment, and Level D does not require any analysis of climate change impacts. This framework provides an organized approach to incorporating projected climate change into the design of arctic infrastructure projects.

16.4.2. Design thawing and freezing indices

Section 16.2.2.2 introduced the concept of air thawing and freezing indices. For design purposes, the design air thawing index (ATI) is commonly defined as the average ATI for the three warmest summers in the latest 30 years of record, or the warmest summer in the latest 10 years of record if 30 years of record are not available (Andersland and Anderson, 1978; Andersland and Ladanyi, 1994).

In Norway, statistical analysis of historic meteorological data is used to determine design air freezing indices (AFIs) with varying probabilities of occurrence (Heiersted, 1976). A similar approach can be used for determining design ATIs in permafrost areas (Instanes, A., 2003).

Table 16.10 shows different design ATIs and their probability of occurrence. The two-year design ATI (ATI_2) is approximately equal to the 30-year mean of the ATI. The average ATI for the three warmest summers in the latest 30 years of record usually lies somewhere between ATI_{20} and ATI_{50}. The magnitude of potential thawing incorporated in a design is dependent on the type of foundation or structure and the consequences of differential settlement or failure. For road embankments, ATI_2 to ATI_{10} is commonly used, while for buildings, ATI_{50} to ATI_{100} is used. For more sensitive structures, such as power plants and oil or gas pipelines, higher design ATIs should be considered.

In thermal analyses using advanced methods such as finite-element models, the design ATI is usually represented by a time series or sine curve that combines an average winter (AFI_2) and a design summer. Maximum thaw depth and permafrost temperature are usually caused by a combination of warm winters and summers. Therefore, combinations of warm winters (low AFI) and warm summers (high ATI) should also be considered.

Section 16.2.2.4 describes projected changes in freezing and thawing indices calculated using output from the ACIA-designated climate models. Figures 16.26 and 16.27 present an example of projected design freezing and thawing indices for Kugluktuk (Coppermine), Canada. The values from 1940 to 2000 are based on observations, while those from 2000 to 2100 are based on output from the CGCM2 model. The figures show curves for the 30-year mean value (probability of occurrence 50%); the mean of the warmest 3 years during the last 30 years; the warmest year during the last 10 years; AFI_{20}/ATI_{20} (probability of occurrence

Table 16.10. Design air thawing indexes (ATIs).

Magnitude of thawing	Probability of occurrence in any given year (%)	Predicted number of occurrences
ATI_2	50	once in 2 years
ATI_{10}	10	once in 10 years
ATI_{20}	5	once in 20 years
ATI_{100}	1	once in 100 years
ATI_{1000}	0.1	once in 1000 years
$ATI_{10\,000}$	0.01	once in 10000 years
Fig. 16.26. Projected air freezing index (AFI) design levels for Kugluktuk (Coppermine), Canada (Instanes A. and Mjureke, 2002b).

Fig. 16.27. Projected air thawing index (ATI) design levels for Kugluktuk (Coppermine), Canada (Instanes A. and Mjureke, 2002b).
5%); AFI_{50}/ATI_{50} (probability of occurrence 2%); and AFI_{100}/ATI_{100}.

Figure 16.26 shows that the 30-year mean design AFI is projected to decrease from approximately 4850 degree-days in 1960 to 3850 degree-days in 2100. This represents an increase in winter (October–March) temperatures of approximately 5 to 6 °C. Figure 16.27 shows that the 30-year mean design ATI is projected to increase from approximately 720 degree-days in 1960 to 1430 degree-days in 2100. This represents an increase in summer (April–September) temperatures of approximately 4 °C. Instanes A. and Mjureke (2002b) presented similar plots of design freezing and thawing indices for the 21 stations listed in Table 16.3.

Using such projections, it is possible to estimate the potential impacts of climate change on specific structures in the Arctic while also including the effect of natural variability. Such an analysis has been carried out

for Svalbard Airport (Instanes A. and Mjureke, in press), using observed air temperature data for 1930 to 2000 and future temperature projections obtained by statistical downscaling of output from the ECHAM4/OPYC3 GSDIO integration (Hanssen-Bauer et. al, 2000, see also section 4.6.2). Figures 16.28 and 16.29 show the results of the analysis. Figure 16.28 shows that average thaw depths are projected to increase by as much as 50% between 2000 and 2050. As Fig. 16.29 shows, March ground temperatures at 2 m depth are projected to undergo the greatest increase (~4 °C) between 2000 and 2050, while the corresponding September temperatures are projected to increase by only 1 °C. At 40 m depth, mean annual temperatures are projected to increase by approximately 2 °C by 2050. At depths of 10 m and more, seasonal temperature variations are small. The climate scenario used in this study projects greater air temperature increases in winter than summer, which contributes to the strong positive trend in March temperatures at 2 m depth. The weak trend in September temperatures at 2 m is largely explained by the proximity of the 0 °C isotherm and the latent heat of the associated phase change. At shorter timescales, the large fluctuations in March ground temperatures reflect variable projected winter conditions, while summer conditions are

Fig. 16.28. Projected thaw depths below the runway at Svalbard Airport (Instanes A. and Mjureke, in press)

Fig. 16.29. Projected ground temperature changes at depths of 2, 10, and 40 m below the Svalbard Airport runway (Instanes A. and Mjureke, in press)

projected to be more uniform. This analysis suggests that the design of structures sensitive to thaw settlement should utilize the risk-based method described in section 16.4.1.

Instanes A. (2003) reported that the design lifetime for structures in permafrost regions is typically 30 to 50 years. Within this time frame, the structure should function according to design with normal maintenance costs. Total rehabilitation, demolition, and replacement of old structures must be expected and are part of sensible infrastructure planning and engineering practice. The effects of climate change on arctic infrastructure are, as previously indicated, difficult to quantify. Structural damage is often blamed on climate change, when a thorough investigation and case history indicates that the cause is either human error or the design lifetime being exceeded.

16.4.3. Coastal areas

Numerous arctic communities face the challenge of increased coastal erosion and warming of permafrost. The combined problems of increased wave action, sea-level rise, and thermal erosion have no simple engineering solutions. Two examples of erosion problems threatening communities and industrial facilities in Canada and Russia are discussed in the following sections. Coastal erosion is discussed in detail in section 6.9.

16.4.3.1. Severe erosion in Tuktoyaktuk, Canada

Tuktoyaktuk is the major port in the western Canadian Arctic and the only permanent settlement on the low-lying Beaufort Sea coast. The location of Tuktoyaktuk makes it highly vulnerable to increased coastal erosion due to decreased extent and duration of sea ice, accelerated thawing of permafrost, and sea-level rise. The Tuktoyaktuk Peninsula is characterized by sandy spits, barrier islands, and a series of lakes that have resulted from collapsed ground due to permafrost thawing ("thermokarst" lakes). Erosion is already a serious problem in and around Tuktoyaktuk, threatening cultural and archeological sites and causing the abandonment of an elementary school, housing, and other buildings. Successive shoreline protection structures have been rapidly destroyed by storm surges and accompanying waves.

As climate change proceeds and sea-level rise accelerates, impacts are likely to include further landward retreat of the coast, erosion of islands, more frequent flooding of low-lying areas, and breaching of freshwater thermokarst lakes and their consequent conversion into brackish or saline lagoons. The current high rates of cliff erosion are projected to increase due to higher sea levels, increased thawing of permafrost, and the increased potential for severe coastal storms during the extended open-water season. Attempts to control erosion at Tuktoyaktuk will become increasingly expensive as the surrounding coastline continues to retreat, and the site could ultimately become uninhabitable.

16.4.3.2. Erosion threatens Russian oil storage facility

The oil storage facility at Varandei on the Pechora Sea was built on a barrier island. Damage to the dunes and beach due to construction and use of the facility accelerated natural rates of coastal erosion. The Pechora Sea coasts are considered to be relatively stable, except where disturbed by human activity. Because this site has been perturbed, it is more vulnerable to damage from storm surges and the accompanying waves that will become a growing problem as climate continues to warm. As with the other sites discussed here, the reduction in sea-ice extent and duration, thawing coastal permafrost, and rising sea level are projected to exacerbate the existing erosion problem. This provides an example of the potential for combined impacts of climate change and other anthropogenic disturbances. Sites already threatened due to human activity are often more vulnerable to the impacts of climate change.

16.4.4. Summary

In areas of continuous permafrost, projected climate change is not likely to pose an immediate threat to infrastructure if the correct permafrost engineering design procedures have been followed; the infrastructure has not already been subjected to one of the factors mentioned at the beginning of this section or strains exceeding design values; and the infrastructure is not located on ice-rich terrain or along coastlines susceptible to erosion. Maintenance costs are likely to increase relative to those at present, but it should be possible to gradually adjust arctic infrastructure (through replacement and changing design approaches over time) to a warmer climate.

Projected climate change is very likely to have a serious effect on existing infrastructure in areas of discontinuous permafrost. Permafrost in these areas is already at temperatures close to thawing, and further temperature increases are very likely to result in extremely serious impacts on infrastructure. However, considerable engineering experience with discontinuous permafrost has been accumulated over the past century. Human activities and engineering construction very often lead to extensive thawing of both continuous and discontinuous permafrost. Techniques to address warming and thawing are already commonly used in North America and Scandinavia.

If the projections and trends presented in this assessment do occur over the next five to ten years, this is very likely to have a serious impact on the future design of engineering structures in permafrost areas. However, engineering design should still be based on actual meteorological observations and a risk-based method.

The most important engineering considerations related to projected climate change include: that risk-based methods should be used to evaluate projects in terms

of potential climate change impacts; that design air thawing and freezing indices should be updated annually to account for observed climate variations and change; and that mitigation techniques such as artificial cooling of foundation soils should be considered as situations require.

In coastal areas, shore protection measures have to some extent reduced local erosion rates. However, thawing and erosion of ice-rich coastal sediments is a process that has been ongoing since the last glaciation and cannot be reversed given present climate trends.

16.5. Gaps in knowledge and research needs

The main gaps in knowledge are the lack of site-specific scenarios providing the probability of occurrence of various meteorological conditions (temperature, precipitation, wind, snow and sea-ice thickness and extent, waves, and erosion rates). Monitoring of infrastructure and the coastal environment is essential, as are climate sensitivity analyses.

It is also important to combine engineering knowledge with socioeconomic development scenarios and environmental impact assessments (see Chapters 3, 12, and 15) to evaluate how projected climate change may affect human lives in the Arctic in the future. Studies examining impacts and socioeconomic assessments have been performed in Canada (Couture et al., 2001). Studies are also underway for other regions of the Arctic, including Alaska (University of Alaska, Institute of Social and Economic Research) and northwest Russia (Centre for Economic Analysis, Oslo; Norwegian Institute of International Affairs, Oslo; and the Fridtjof Nansen Institute, Bergen).

Summary

Climate change occurs amid myriad social and natural transformations. Understanding and anticipating the consequences of climate change, therefore, requires knowledge about the interactions of climate change and other stresses and about the resilience and vulnerability of human–environment systems that experience them. Vulnerability analysis offers a way of conceptualizing interacting stresses and their implications for particular human–environment systems. This chapter presents a framework for vulnerability analysis and uses this framework to illuminate examples in Sachs Harbour, Northwest Territories, Canada; coastal Greenland; and Finnmark, Norway. These examples focus on indigenous peoples and their experiences or potential experiences with climate change, organic and metallic pollution, and changing human and societal conditions. Indigenous peoples are the focus of these studies because of their (generally) close connections to the environments in which they live and because of the coping and adaptive strategies that have, for generations, sustained indigenous peoples in the highly variable arctic environment. The Sachs Harbour and Greenland examples are cursory since vulnerability field studies in these areas have yet to be undertaken. The Finnmark example provides a more in-depth analysis of Sámi reindeer herding developed through a collaborative effort involving scientists and herders, a subset of whom are authors of this chapter. These examples reveal a number of factors (e.g., changes in snow quality, changes in ice cover, contaminant concentrations in marine mammals, regulations, resource management practices, community dynamics, and economic development) likely to be important in determining the vulnerability of arctic peoples experiencing environmental and social change. The examples also illustrate the importance of understanding (and developing place-based methods to refine this understanding) stress interactions and the characteristics of particular human–environment systems, including their adaptive capacities. Moreover, meaningful analyses of human–environment dynamics require the full participation of local people, their knowledge, perspectives, and values.

Full vulnerability assessments for communities in Sachs Harbour and coastal Greenland, require in-depth investigations into what the people living in these areas view as key concerns and how these residents perceive the interrelations among, for example, natural resources and resource use, climate change, pollution, regulations, markets, and transnational political campaigns. This information will contribute to the identification of relevant stresses and to analysis of adaptation and coping, historically, presently, and in the future. For the Finnmark case study next steps should include attaining a more complete understanding of interrelations among reindeer herding, climate change, and governance and how reindeer herders might respond to consequences arising from changes in these factors. This case study highlights a number of other areas for future and/or continued investigation. These include analysis of the possibility that governmental management authorities or herders might respond to environmental and social changes in ways that enhance or degrade the reindeer herding habitat, and a more in-depth inquiry into extreme events and their implications for sustainable reindeer herding.

A comprehensive picture of the vulnerability of arctic human–environment systems to climate change and other changes will benefit from further development of case studies, longer periods of longitudinal analysis, and more comprehensive research with interdisciplinary teams that include local peoples as full participants. Case studies should be selected to provide information across a wide array of human–environment systems and conditions so as to enable comparative work across sites. This will lead to refinements in the vulnerability framework and improved understanding of resilience and vulnerability in this rapidly changing region.

17.1. Introduction

The impact assessments in the preceding chapters demonstrate significant effects that climate change and increases in ultraviolet (UV) radiation are now having and are expected to have on arctic peoples and ecosystems. These chapters also illustrate that (1) climate change and increases in UV radiation occur amidst a number of other interacting social and environmental changes, (2) the consequences of social and environmental changes depend on the interconnectedness of human and environmental systems and the ability of these coupled systems to cope with and otherwise respond to these changes, and (3) these changes and their consequences occur within and across scales from local to regional and even global dimensions (NRC, 1999). Assessments of potential impacts of social and environmental change in the Arctic will benefit from formalized frameworks for conceptualizing and analyzing these three characteristics and their implications for the dynamics of arctic social and biophysical systems. The fund of knowledge and learning that underpins these frameworks is based in risk–hazard and vulnerability studies, but only in recent years have these frameworks been applied in studies of arctic human and environment systems. Thus, unlike earlier chapters, this chapter does not have the benefit of a large body of published literature from which conclusions can be drawn regarding the resilience of arctic peoples and ecosystems in relation to future climate change and its interactions with other social and environmental changes.

This chapter develops the case for using a vulnerability framework to explore these interactions and ultimately to generate understanding as to where resilience, made possible through coping and adaptive strategies, could be effective in diminishing future climate change impacts in arctic coupled human–environment systems. "Coupled human–environment system" refers to the ensemble of inextricable relationships linking people and the environment within which they live. Use of the word "system"

should not complicate this term, but rather it should communicate that various elements, from politics and history to the behavior of individuals and the ecology of plants and animals, form a complex whole. A vulnerability analysis that builds upon the assessment of climate impacts will consider a climate event in the context of other stresses and perturbations that together produce impacts of a compound character (Kasperson J. and Kasperson, 2001). Elements of a vulnerability approach are evident throughout preceding chapters of this assessment. The concept of vulnerability itself is noted in Chapters 1, 3, and 12, and adaptation and resilience are important themes in the overall assessment, particularly in Chapters 1, 3, 7, 11, 12, and 13.

This chapter uses the definitions of vulnerability and its elements that were adopted in the Third Assessment Report of the Intergovernmental Panel on Climate Change with vulnerability defined as the degree to which a system is susceptible to, or unable to cope with, adverse effects of stresses. Vulnerability is a function of the character, magnitude, and rate of change in stresses to which a system is exposed, its sensitivity, and its adaptive capacity. Exposure is the degree to which a system is in contact with particular stresses. Sensitivity is the degree to which a system is adversely or beneficially affected by stimuli. And adaptive capacity (or resilience) refers to a system's ability to adjust, to moderate possible harm, to realize opportunities, or to cope with consequences (IPCC, 2001b).

The presentation of vulnerability analysis in this chapter rests on three primary assumptions: (1) arctic human–environment systems are experiencing multiple and interacting stresses in addition to changes in climate and UV radiation; (2) consequences of social and environmental change depend upon how human–environment systems respond to such changes; and (3) the dynamics of changes, adaptations, and consequences span varied scales. Climate change and UV radiation increases trigger changes in ecosystems upon which arctic residents depend. For example, global warming is expected to increase net primary productivity in terrestrial and freshwater ecosystems (IPCC, 2001b; see also Chapters 7 and 8), but increased UV radiation penetration is likely to adversely affect productivity in aquatic ecosystems (AMAP, 1998). Although the Arctic is still a relatively pristine environment compared with many other areas, this region is experiencing significant problems associated with contaminants such as persistent organic pollutants (POPs) and heavy metals (AMAP, 1998, 2002). Climate change and exposure to pollutants interact, since changes in ice cover and runoff can cause lakes to become greater sinks for river-borne contaminants, and increased catchment rates and melting ice can lead to wider dispersion of pollutants. Moreover, sea-ice reductions can speed the entry of POPs trapped in Arctic Ocean ice into the food chain, posing risks to humans (AMAP, 2003; IPCC, 2001b). Linked human health effects of UV radiation, arctic diets, and pollutants have received little attention, but are plausible (De Fabo and

Björn, 2000). Clearly, an assessment of arctic vulnerabilities and the adaptive capacities that can modify vulnerabilities requires a holistic understanding of multiple drivers of change and their interactions.

Examples of resilience are also illustrated in the preceding chapters of this assessment. Consequences arising from climate change and increased UV radiation depend in large part both on the interconnectedness of human–environment systems and the capacities of these systems to respond to changes (see especially Chapters 1, 3, 7, 11, 12, 13; Freeman, 2000; Stenbaek, 1987). As noted by the authors of the Mackenzie Basin Impact Study:

> *Traditional lifestyles could be at risk from climate change, but this new challenge will not occur in a vacuum. Population growth and economic and institutional changes will influence the North's sensitivities and vulnerabilities to climate variability and climate change. They will also influence how regions and countries respond to the prospects of a global scale phenomenon that could affect their climate no matter what they do on their own.* Cohen, 1997

Studies of some regional arctic seas have also considered changes in factors that will interact with climate change. One such example is the Barents Sea Impact Study, which examines the possible mobilization of contaminants on the Kola Peninsula. The success of the Barents Sea Impact Study rests on a number of factors including place-based research that addresses socio-economic factors, the inclusion of indigenous knowledge, and attention to cross-scale interactions (Lange et al., 2003).

How arctic peoples experience, respond to, and cope with environmental phenomena will be shaped to some degree by the social changes they have experienced in the past (Freeman, 2000; Stenbaek, 1987; Chapters 1, 3, 11, 12, 13). Increasingly these changes concern relationships between local and central governments (Chapter 3), ties to a global economy and external markets and ways of life (Chapters 11 and 12), campaigns relating to animal rights and environmental issues (Chapter 12), resource management systems grounded in transnational as well as domestic policy fora (Chapters 11, 12, 13), habitat loss due to urbanization, industrial development, and agriculture (Chapter 11), and extraction of non-renewable resources (Chapters 11, 12, 16). Additional contemporary concerns of high priority for arctic peoples include poverty, domestic violence, substance abuse, inadequate housing, and substandard infrastructure (Chapters 3, 15, and 16).

Analysis of these and other changes and their implications for arctic human–environment systems must take account of dynamics at different scales. Some changes, such as those associated with climate change, for example, originate outside the Arctic, and arctic peoples contribute little to their sources. At the same time, the lives of many arctic peoples are closely interconnected with their environments through fishing, hunting, herd-

ing, and gathering (see Chapters 3 and 12). These relationships are also evolving, through, for example, technological changes, which can influence the future sustainability of arctic livelihoods. These close ties to transnational processes and intimate relationships between many arctic people and their environments underscore the importance of examining the vulnerability of particular arctic human–environment systems within the context of dynamics operating within and across local, regional, and global levels.

Social and environmental changes often yield benefits, as well as adverse effects for human–environment systems (Chapter 12). It is, therefore, appropriate to ask: in addition to the obvious desire to minimize future adverse effects of climate and other changes, in what ways might new opportunities be realized? Climate change could lead to increased vegetation growth/cover (Chapter 7), increased production of reindeer meat, new trade routes (Chapter 12), and new or intensified forms of commercial activity. Innovations in hunting equipment and practices might enable some hunters to hunt even more effectively and sustainably under snow and ice cover alterations brought about by climate change. Hunters may adapt to climate change by changing the type of species that they hunt and by altering the location, timing, and intensity of hunting. They may also take actions to minimize risk and uncertainty under unpredictable climate and ice conditions (e.g., by taking greater safety precautions or by electing not to hunt or fish) (Chapter 12).

The integrated vulnerability analysis described in this chapter begins with a general framework from Turner et al. (2003a). This framework provides a means of conceptualizing the vulnerability of coupled human–environment systems, under alterations in social and biophysical conditions arising from and interacting across global, regional, and local levels (e.g., NRC, 1999). Two examples are given where the extension of a climate impact analysis to a vulnerability analysis would be a logical next step. An example of a fully participatory exercise with a Sámi reindeer herding community in the Finnmark area of northern Norway is then used to explore aspects of vulnerability in their reindeer-herding livelihood. A full understanding of vulnerability in any of the systems examined is beyond the scope of this chapter. Such an analysis would require in-depth fieldwork and extensive participation of arctic residents (e.g., in planning and carrying out the assessment, in determining the stresses of greatest concern to them, in generating and disseminating results, etc.). The initial phase of work presented here illustrates, however, preliminary results of a conceptual and methodological approach to vulnerability analysis. These results offer insights into: the vulnerability of particular arctic human–environment systems to multiple human and environmental changes, how human and environmental conditions and behavior might attenuate or amplify these changes and their consequences, and what options exist to reduce vulnerability (see Turner et al., 2003a).

Examples used in this chapter focus on the experiences and likely future prospects for indigenous communities and the environments upon which they depend. Although non-indigenous populations far outnumber indigenous peoples in the Arctic, there are a number of reasons why a focus on indigenous livelihoods is particularly suited for initial analyses of interactions between climate and other factors that can contribute to the vulnerability of arctic residents. First, analyses of vulnerability require an understanding of human–environment interactions and their historical evolution. Such connections can be complex and difficult to discern. Indigenous ways of life, however, often offer ready insights into the ways in which people depend upon and adapt to their surroundings. Many indigenous peoples, for example, have livelihoods based partly or wholly on subsistence activities that entail strong human–environment relationships that have persisted through many generations. These activities include hunting, fishing, herding, and/or gathering, and their execution requires knowledge about the highly variable arctic environment, how to interact and cope with it, and how earlier generations adapted to past changes (Krupnik and Jolly, 2002). Second, analyses of vulnerability have the greatest potential for informing decisions regarding adaptation and mitigation when there is a distinct possibility of social and environmental loss. Arguably, the potential for such loss is particularly acute in indigenous arctic communities as they encounter varied forms of environmental and social change.

Rates of climate changes projected for some regions of the Arctic exceed, however, those likely to have been experienced during multiple past human generations. Thus, the resiliencies sufficient during the past may or may not suffice in the future. Moreover, while not all forms of likely future change portend likely negative consequences, climate change, UV radiation exposure, transboundary air pollution, and economic globalization, singly and in combination have the potential to adversely affect long-standing indigenous cultural practices, livelihoods, economies, and more. It is also noteworthy that among arctic residents a much larger body of literature is available on the resilience of indigenous peoples' livelihoods in response to climate change and in the context of multiple stressors.

The prospect of climate change in the Arctic has now begun to seriously influence planning in this region. Over an even shorter period researchers have begun to explore the degree to which likely future climate change will interact with other factors in the broader realm of human–environment interactions. At this early stage in the development of methodologies to quantitatively assess the vulnerability of different aspects of the human–environment system, studies of indigenous arctic communities are timely. Studies of indigenous peoples in other areas can now provide a common context within which to test characterizations of human–environment systems and their interactions, and to advance integrative data collection and analytical methodologies. Notable among these approaches is the

absolute necessity of co-generating knowledge of exposures, sensitivities, and resiliencies inherent in these systems by involving indigenous peoples at the earliest stages of research planning and analysis.

Analyses of indigenous communities can also yield insights into the lives and livelihoods of non-indigenous arctic residents. However, without the same degree of historical and cultural ties to localities and ways of life, and with greater freedom to relocate, perhaps to an area outside the Arctic, non-indigenous residents will be vulnerable to likely future change in the Arctic in different ways. Eventually, suites of case studies focused on indigenous peoples and non-indigenous peoples and their environments will form useful comparative analyses from which questions regarding comparative resiliencies and ultimately their relative vulnerabilities can be assessed.

17.2. Conceptual approaches to vulnerability assessments

Large-scale studies of climate impacts have begun to examine the vulnerability of social and ecological systems to climate change. The seminal work of Timmerman (1981) provided intellectual underpinning for linking the concepts of vulnerability, resilience, and climate change. Examples of recent projects that incorporate these perspectives include the IPCC (particularly the contribution of Working Group II to the Third Scientific Assessment; IPCC 2001b), the Assessments of Impacts of and Adaptation to Climate Change in Multiple Regions and Sectors (AIACC) implemented by the United Nations Environment Programme, the Finnish global change research projects FIGARE and SILMU, the European Commission project on Tundra Degradation in the Russian Arctic (TUNDRA), the Norwegian project NORKLIMA, the US National Assessment of Climate Change Impacts on the United States (NAST, 2000), and the Regional Vulnerability Assessment (ReVA) Program under the United States Environmental Protection Agency (Smith, 2000). Some of these assessments were based on published research, and as such are limited in their completeness with respect to their spatial coverage, and especially to their inclusiveness of other stressors that can interact with climate to influence the vulnerability of human–environment systems. Other assessments are underway, and the surge in vulnerability research over the last few years will ensure that future climate impact assessments are more complete with respect to interactions with other stressors.

Vulnerability analysis is rooted in a long history (e.g., Cutter, 1996; Dow, 1992; Downing, 1992; Kates, 1971; Liverman, 1990; Turner et al., 2003a; White, 1974), and in research traditions (for recent reviews see Cutter, 1996; Golding, 2001; Kasperson J. et al., 2003; Polsky et al., 2003; Turner et al., 2003a) that encompass work on risk–hazards–disasters (Blaikie et al., 1994; Cutter, 1996), climate impacts (Cutter, 2001; IPCC, 1997; Kates et al., 1985; Parry 1978; Parry et

al., 1998), food security (Böhle et al., 1994; Downing, 1991; Easterling, 1996), national security (Bachler, 1998; Dabelko and Simmons, 1997; Gilmartin et al., 1996; Homer-Dixon and Blitt, 1998; Winnefield and Morris, 1994), and resilience (Berkes and Folke, 1998; Berkes et al., 2003; Turner et al., 2003a). Much of the applied hazards, climate impact, and food security research to date has focused on the source of and potential exposure to a hazard, and has sought to understand the magnitude, duration, and frequency of this hazard and the sensitivity of the exposed system (Burton et al., 1978; Cutter, 1996).

It is common to distinguish between impacts and vulnerability perspectives by saying that the former focuses more on system sensitivities and stops short of specifying whether or not a given combination of stress and sensitivity will result in an effective adaptation. The latter emphasizes the factors that constrain or enable a coupled human–environment system to adapt to a stress. Another distinction that has been drawn between climate impact and vulnerability assessments is that the former proceeds by examining a climate event and the stresses that are exerted upon an exposure unit to produce critical downstream outcomes. The latter, by contrast, considers the climate event in the context of other stresses and perturbations that together produce impacts from compound events (Vogel as quoted in Kasperson J. and Kasperson 2001).

These distinctions are, however, to some degree oversimplifications, since a lack of emphasis on adaptation applies more to past empirical studies of climate change impacts than to the conceptual underpinnings of such studies. Adaptation has long been at the heart of the debate on reducing vulnerability to environmental stresses (Turner et al., 2003a). Even the early models on climate change impacts (e.g., Kates et al., 1985) consider the importance of adaptation, and the same applies to the broader, related literature on risk/hazards (e.g., Burton et al., 1978; Cutter, 1996; Kasperson R. et al., 1988) and food security (e.g., Böhle et al., 1994; Downing, 1991). Parry and Carter (1998) also acknowledge the seminal ideas of Kates (1985) on this topic and go on to discuss the evolution from a climate impact approach to a climate interaction approach. They describe how the severe economic hardship experienced by Canadian prairie farmers in the 1930s arose as a result of interaction among multiple factors. "Economics, weather and farming technology interacted to create a severe economic and social impact that was perhaps preconditioned by the Depression but triggered by drought."

Thus, increasing interest in "global change vulnerability" is not so much the result of a revolution in ideas – although the theoretical bases are maturing (e.g., Adger and Kelly, 1999) – but more a response to a general dissatisfaction with the ways in which adaptive capacity has been captured in empirical research and the associated need to reconnect with this concept if climate impact and global change models are to improve.

Increasingly, studies of vulnerability go beyond understanding the behavior of a stress and the degree to which an exposed system reacts adversely or beneficially (Holling, 1996, 2001). These studies also investigate (1) ways in which the exposed system might respond to, intensify, and/or ameliorate the effects of multiple stresses; and (2) why the same hazard might affect different systems in different ways and what system characteristics (including political economy, social structures and institutions) help to explain this variation. The concept of resilience in ecological studies has also informed treatment of adaptive capacity in vulnerability assessment (Resilience Alliance, no date; Walker et al., 2002). Resilience generally refers to the ability of a system to return to a reference state or remain within a range of desirable states following a perturbation. Berkes and Jolly (2001) have pointed out that the concept of resilience has three defining characteristics. It is a measure of: the amount of change the system can experience and still retain the same controls on function and structure; the degree to which the system is capable of self-organization; and the systems' ability to sustain and increase its capacity for adaptation.

Similarly, adaptive capacity refers to ecosystem flexibility and social system responsiveness in the face of disturbances (Turner et al., 2003a). According to one line of thought in political ecology, for example, adaptive capacity derives from human ecology of production, entitlements pertaining to market exchanges, and political economy (Böhle et al., 1994). These factors depend, for example, on resources available to a social group, the ability to sell these resources, the selling price, and access to markets (Sen, 1981). In addition, social, institutional, and political conditions might affect the ability of a social system to utilize resources or make other adjustments in overcoming the effects of a disaster such as drought (Turner et al., 2003a). Initiatives such as the Management of Social Transformations Programme's Circumpolar Coping Processes Project (MOST CCPP) advances understanding of human responses to environmental and other forms of change. MOST CCPP is a cross-disciplinary network comprising participants from Norway, Finland, northwest Russia, Denmark, Faroe Islands, Greenland, Iceland, Canada, and Sweden. This project is a comparative research endeavor that examines ways in which local authorities, civil society actors, and enterprise networks cope locally and regionally with global technological, economic, and environmental changes.

Researchers are also increasingly attentive to the socio-ecological, multi-scalar, and dynamic nature of vulnerability. Studies aimed at understanding the vulnerability of particular places are forgoing the tendency to treat social and biophysical vulnerability as separate conditions (e.g., see Adger and Kelly, 1999; Kelly and Adger, 2000). They are instead examining the vulnerability of the coupled human–environment system with place-based approaches (Cutter, 1996; Turner et al., 2003a) (also see Berkes and Folke, 1998; Berkes et al., 2003).

In addition, conditions and phenomena spanning global, national, and local levels can have important implications for the vulnerability of specific people and areas. For example, the globalization of markets, technological innovations originating abroad, changes in national policy, and the condition of local infrastructure could all potentially increase or decrease the vulnerability of a particular household or community to drought or flood (Leichenko and O'Brien, 2002). The ever-changing character of biogeophysical, environmental, institutional, economic, and political processes that influence human–environment systems requires that vulnerability be treated as a process (Handmer et al., 1999; Leichenko and O'Brien, 2002; Reilly and Schimmelpfenning, 1999). In its simplest static state vulnerability can be seen as the residual of change after considering the resilience and adaptive capacity of a system. However, the dynamic nature of these processes requires that vulnerability also be considered as an integral part of the change rather than external to it.

17.2.1. A framework for analyzing vulnerability

Building on this history, the combined effects of climate and other stressors can be examined via the following questions:

1. How do social and biophysical conditions of human–environment systems in the Arctic influence the resilience of these systems when they are impacted by climate and other stressors?
2. How can the coupled condition of these systems be suitably characterized for analysis within a vulnerability framework?
3. To what stresses and combinations of stresses are coupled human–environment systems in the Arctic most vulnerable?
4. To what degree can mitigation and enhanced adaptation at local, regional, national, and global scales reduce vulnerabilities in these systems?

Answers to these questions require a holistic research approach that addresses the interconnected and multi-scale character of natural and social systems. A framework for this approach (Fig. 17.1) depicts a cross-scale, coupled human–environment system. The multiple and linked scales in each diagram are reflected in the nesting of different colors with blue (place), pink (region), and green (world). The place (whatever its spatial dimensions) contains the coupled human–environment system whose vulnerability is being investigated. Figure 17.2 presents a more detailed schematic of the place. The influences (including stresses) acting on the place arise from outside and inside its borders. However, given the complexity and possible non-linearity of these influences, their precise character (e.g., kind, magnitude, and sequence) is commonly specific to the place-based system. This system has certain attributes denoted as human and environmental conditions. These conditions can interact with one another and can enable or inhibit cer-

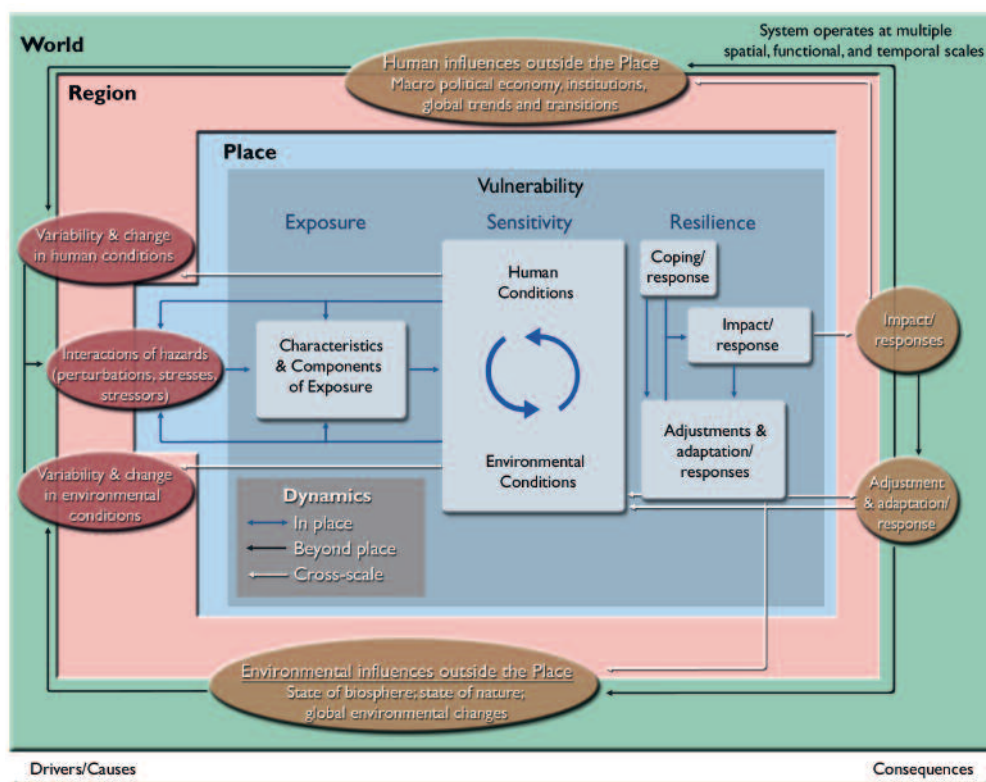
tain responses in, for example, the form of coping, adaptation, and impacts. Negative impacts at various scales result when stresses or perturbations exceed the ability of the place-based human–environment system to cope or respond. There are a number of feedbacks and interactions within and around the place-based system and these dynamics can extend across place-based, regional, and global levels. Impacts and mitigating and adaptive responses, for example, can modify societal conditions of the place and/or alter societal and environmental influences within the place and at regional and global scales.


Fig. 17.1. Vulnerability framework (Turner et al., 2003a).

The vulnerability of the coupled human–environment system can be thought of as the potential for this system to experience adverse impacts, taking into consideration the system's resilience. Adverse impacts might arise from phenomena such as climate change, pollution, and social change. The system's resilience depends on its ability to counter sources of adverse change and to adapt to and otherwise cope with their consequences. It is important to note differences between mitigation and adaptation. Mitigation involves the amelioration of a stress at its source (e.g., changes in fossil fuel consumption resulting in reduced greenhouse gas (GHG) emissions). While the Arctic is experiencing the effects of climate change, actions to mitigate climate change through GHG reductions are largely dependent on the actions of people living at more southern latitudes. Adaptation (e.g., through mobility, new hunting or fishing practices, and/or the development or adoption of new technologies) requires that resources and other forms of capacity be accessible to the human–environment system in question. Such resources and capacity can take years, even generations to develop.

17.2.2. Focusing on interactive changes and stresses in the Arctic

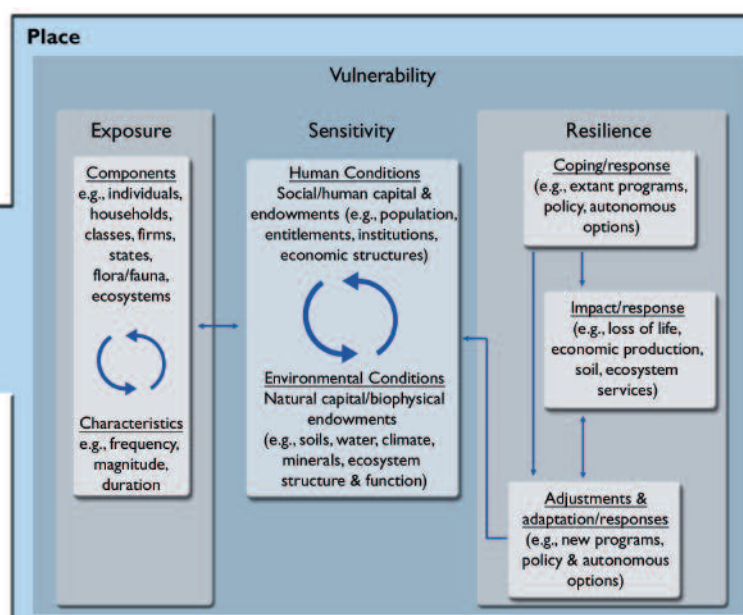
The Arctic is experiencing a number of striking social and environmental changes and influences. While some are welcome, others (considered stresses) have adverse consequences. Given that vulnerability is highly complex and can vary significantly with location, it is essen-


Fig. 17.2. Details of the exposure, sensitivity, and resilience components of the vulnerability framework (Turner et al., 2003a).

tial to conduct "place-based" analyses, where "place-based" suggests a spatially continuous set of human–environment conditions or systems (Turner et al., 2003a). Since the vulnerability of a system is closely connected to the particular social and environmental conditions at a given location, the priorities and perspectives of people living in the location and those of other stakeholders are essential for identifying the key stresses, and understanding the exposure, sensitivity, and resilience of their coupled human–environment system (see section 17.3.4). Thus, knowledge, values, and

understanding held by local residents are integral in determining which factors are most likely to test resilience of a system. Recent research on coupled human–environment systems (Turner et al., 2003a,b) demonstrates the efficacy of a participatory approach. The Sachs Harbour and Finnmark examples discussed in this chapter similarly evidence the importance of collaborating with local people and other stakeholders.

Preliminary consultations with arctic researchers and residents led the authors of this chapter to consider environmental pollution (POPs and heavy metals) and trends in human and societal conditions in addition to climate change and variability and UV radiation as potential stressors in arctic human–environment systems. The case for climate change is central to the Arctic Climate Impact Assessment, and so needs only a brief review in this section. Changes in UV radiation also receive considerable attention in the ACIA, but rather less is known about how possible harmful effects will be distributed in the Arctic. So little can be done at this time to assess vulnerability to this potential stress either in isolation or in combination with other factors. The comprehensive nature of the Arctic Monitoring and Assessment Programme (AMAP) studies allow much more to be said about organic and metal pollution as a potential stress in arctic systems, so more attention is given to pollution in this section.

It is important to note that, although they are often referred to here as stresses, climate change and trends in human and societal conditions can have positive as well as negative effects. Changes in climate and climate variability refer to changes in temperature, precipitation, snow cover, permafrost, sea ice, and extreme weather events. Major POPs include DDT (Dichlorodiphenyl-trichloroethane), PCBs (polychlorinated biphenyls), HCH (hexachlorocyclohexane), and major heavy metals include lead (Pb), cadmium (Cd), and mercury (Hg) (AMAP, 1998, 2002). Human and societal trends of interest are consumption (especially pertaining to food-stuffs and technology), settlement patterns and demography, governance and regulation (particularly regarding natural renewable resources), connectivity (e.g., telephones, email, Internet), and markets and trade (Turner et al., 2003b) (see also Beach, 2000; Bjerregaard, 1995; Caulfield, 1997, 2000; Kuhnlein and Chan, 2000; Macdonald et al., 2003; Stenbaek, 1987; Svensson, 1987a,b; Wheelersburg, 1987). More in-depth fieldwork and analysis might reveal additional high priority stresses important for these sites.

17.2.2.1. Trends in human and societal conditions

Arctic peoples have experienced significant social changes over the past few human generations (Freeman, 2000; Stenbaek, 1987) as the Arctic's borders have become more permeable to southerners, material goods, and ways of thinking; as indigenous peoples have asserted their identity, rights, and culture in legal and policy forums; and as new relationships have formed

between local and national governments. The Arctic Council's Arctic Human Development Report (AHDR, 2004), especially its chapters on sustainable human development and economies is a logical and welcome next step in a synthesis of understanding in this area. Technology has been an important part of many such transformations. Satellites, television, the Internet, and telephones, for example, have revolutionized communication. Snowmobiles, all terrain vehicles, and more powerful small boats have brought new modes of transportation and recreation while accompanying changes in some hunting, herding, and fishing practices. The modernization of hunting equipment has also contributed to changes in approaches to whaling and marine mammal hunting. Individuals often have differing views about what types of social changes are beneficial and what types are unwanted. Some arctic residents, for example, might support the use of snow-mobile technology in reindeer herding, while others might oppose it. Similarly, some people might view certain forms of human and societal change as adversely stressing a human–environment system, while others might view these changes as enhancing the resilience of that system. In seeking to understand how such changes bear on the vulnerability of arctic communities, this chapter examines a variety of human and societal factors including governance, population dynamics, migration, consumption, economies, markets and trade, and connectivity. These represent only a small subset of topics that constitute human and societal conditions. In some instances these factors are considered influences or stresses on the system (e.g., regulations limiting flexibility in reindeer herding). In other instances these factors can serve as both influences and part of the system's adaptive and coping responses (e.g., migration and changes in consumption).

17.2.2.2. Climate change

Projections of future climate change in the Arctic are documented in Chapter 4. Temperatures are projected to increase throughout the Arctic, even in sub-regions that have shown slight cooling trends in the latter half of the 20th century. Summer sea ice in the Arctic Ocean is projected to continue to decrease in area and thickness. The active layer of permafrost is projected to continue to deepen. Seasonal weather and precipitation patterns are likely to change, altering forms of precipitation between rain, freezing rain, and snow, and affecting snow quality. Recent evidence indicates that many of these changes are already affecting the distribution and abundances of terrestrial and marine species (see Chapters 7, 8, 9). Changes in temperature, precipitation, and storm patterns can affect the type, abundance, and location of animals and plants available to humans and may lessen the productivity of certain traditional forms of hunting and gathering. Decreases in the extent and thickness of sea ice can alter the distribution, age structure, and size of marine mammal populations, expose the arctic coast to more severe weather events, exacerbate coastal erosion, and affect modes of transportation and the ability of peo-

ple to reach hunting locations and other villages. Changes in surface water budgets and wetlands can change coastal microclimates, alter the size and structure of peatlands, and result in pond drainage. In addition, damp, wet air during the traditional "drying season" makes it difficult to dry and preserve foods for winter months. These changes would, in turn, result in effects felt not only in human communities in the Arctic, but in other areas of the world as well (IPCC, 2001b).

17.2.2.3. UV radiation

Continued ozone depletion and the related problems of UV radiation exposure are likely to result in serious human and ecosystem impacts (Cahill and Weatherhead, 2001). UV radiation can harm humans directly via sunburn and skin cancer, immune system suppression, and eye damage, such as cataract photokeratitis (AMAP, 1998; De Fabo and Björn, 2000). The synergistic effects of UV radiation, climate change, and pollution could be more intense than the effects of any one of these stresses acting alone. For example, aquatic organisms that have assimilated UV-B absorbing polyaromatic hydrocarbons have shown phototoxic effects when exposed to UV-B radiation. Exposure to UV radiation has also been found to increase the toxicity of some chemicals, especially those associated with oil spills (Cahill and Weatherhead, 2001).

Adverse effects of UV radiation on arctic plants and animals can also indirectly affect humans. The vulnerability of arctic ecosystems to UV radiation is greatest in spring when ozone depletion is at its maximum and when new organisms are beginning life. Arctic plants have fewer protective pigments and are more sensitive to UV radiation than similar plants in other regions of the world, partly because at low temperatures plants are less able to repair UV radiation damage (AMAP, 1998; De Fabo and Björn, 2000).

Wildlife can experience UV radiation effects similar to those found in humans, although fur and plumage mean skin effects are less likely than eye damage (De Fabo and Björn, 2000). Increased UV radiation may affect fisheries through changes in planktonic food webs, but these changes are difficult to predict because they involve long-term alterations in species adaptation and community structure. If UV radiation were to change arctic aquatic ecosystems, this could in turn affect seabirds and land predators (e.g., seals, foxes, and bears) that feed on aquatic organisms (AMAP, 1998).

17.2.2.4. Pollution

AMAP concluded in both of its two recent assessments that pollution can pose problems in the Arctic (AMAP, 1998, 2002). Heavy metals and POPs are of particular concern, although there are important regional and local variations within the Arctic. Both heavy metals and POPs are transported to the Arctic via long-range air and water pathways and both bioaccumulate in food

webs (see Fig. 17.3) (AMAP, 2002; Wania and Mackay, 1996). In addition to long-range transport, some pollutants originate from local sources such as the geology, industrial activities, pesticide use, and private use.

Heavy metals and POPs are associated with several environmental risks. These include estrogenic effects, disruption of endocrine functions, impairments of immune system functions, functional and physiological effects on reproduction capabilities, and reduced survival and growth of offspring (AMAP, 1998, 2002; UNECE, 1994). Data on human health effects suggest that human exposure to levels of POPs and heavy metals found in some traditional foods may cause adverse health effects, particularly during early development (AMAP, 2003; Ayotte et al., 1995; Colborn et al., 1996; Hild, 1995; Kuhnlein and Chan, 2000).

Traditional foods also provide health benefits, however, which need to be weighed against risks (see section 17.2.3.3). Many traditional foods are rich in vitamins and nutrients and low in saturated fats. Whale skin and blubber, for example, are a good source of vitamins A and C, thiamin, riboflavin, and niacin. They are also low in saturated fats and high in omega-3 polyunsaturated fatty acids that guard against cardiovascular diseases. Additional health benefits arise from the physical activity required to obtain traditional foods. Moreover, traditional harvesting, processing, and sharing of traditional foods serve important roles in the social, cultural, and economic life of many arctic inhabitants (AMAP, 2003; Freeman et al., 1998). In communities where contaminant levels are sufficiently high to prompt health concerns, balanced dietary advice is needed, especially for pregnant women and small children. Risk–benefit discussions have been most productive when they involve local communities, local public health authorities, and experts from a wide array of disciplines (AMAP, 2002, 2003).

Persistent organic pollutants that require special attention in arctic vulnerability studies include the industrial chemicals PCBs; the pesticide DDT; and the pesticide HCH, the most common form of which, γ-HCH, is the insecticide Lindane. These are well-known arctic pollutants of concern (AMAP, 1998, 2002) that are currently being addressed by national legislation and international agreements (Downie et al. 2004; Eckley, 2001; Selin, 2003; Selin and Eckley, 2003).

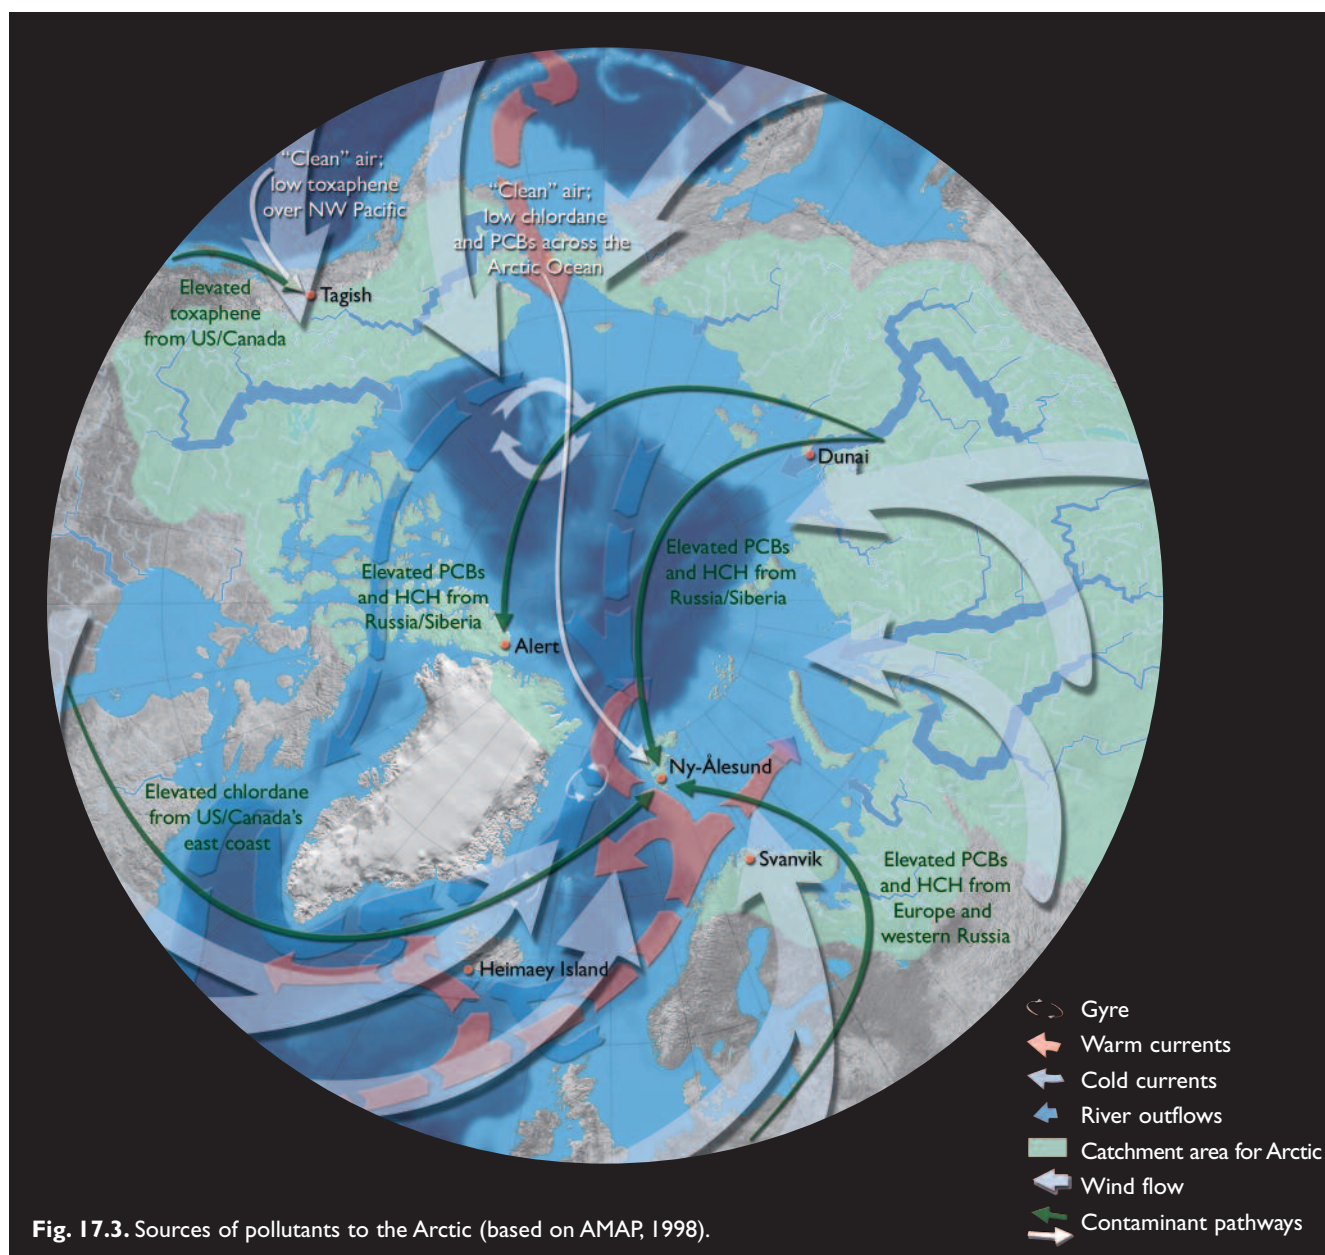
Many other POPs are known to be hazardous, as well as possibly other, lesser known organic substances that may have negative impacts. For example, levels of the flame-retardants polybrominated diphenyl ethers (PBDEs), polychlorinated naphthalenes (PCNs), and the pesticide endosulfan are increasingly found in the Arctic. Levels of PBDEs are increasing in the Canadian Arctic (AMAP, 2002; Ikonomou et al., 2002). Ikonomou et al. (2002) suggested that at current rates of bioaccumulation, PBDEs will surpass PCBs to become the most prevalent contaminant in ringed seals (*Phoca hispida*) in the Canadian Arctic by 2050.


Fig. 17.3. Sources of pollutants to the Arctic (based on AMAP, 1998).

For heavy metals, special attention should be given to Cd, Pb, and Hg. The rationale for selecting these heavy metals is similar to the rationale for selecting the POPs; they are well known arctic pollutants that have been subject to much previous study (AMAP, 1998, 2002). They are also being addressed by national legislation and regional international agreements. Heavy metals are naturally-occurring environmental trace elements, and many are essential elements for living organisms. However, some have no known metabolic roles, and some are toxic even at low exposures. In the last 150 years there have been changes in the form in which these metals are released and dramatic increases in the quantity of these metals emitted to the environment. Anthropogenic emissions have altered the natural biogeochemical cycles of these elements (Nriagu, 1996). Anthropogenic sources of heavy metal pollution include industrial production, combustion processes, and waste incineration. These anthropogenic inputs add to the natural background levels

and can pose a toxic risk to environmental and human health (AMAP, 2002).

17.2.2.5. Pollutant interactions

Climate change, pollution, and human and societal conditions are interrelated and the consequences of these phenomena will depend largely on their interactions. It is becoming increasingly clear, for example, that climate change and pollution interact closely and that climate changes can affect the pollution transport chain (Alcamo et al., 2002). Air current changes affect pollutant transport patterns. Temperature changes affect which pollutants are deposited where, how they migrate, and which animals accumulate which pollutants. More extensive melting of multi-year sea ice and glacial ice can result in pulse releases of pollutants that were captured in the ice over multiple years or decades (AMAP, 2002; Macdonald et al., 2003).

Recently discovered mercury depletion events (MDEs) in the high Arctic (Schroeder et al., 1998) reflect additional ways in which pollution interacts with other factors. Levels of gaseous elemental mercury drop sharply each spring following polar sunrise, in a series of events that begin shortly after the first sunrise and continue until the snow melts. These MDEs are highly correlated with depletions in surface ozone, and appear to be caused by a reaction involving sunlight and bromine. The gaseous elemental mercury is transformed into reactive gaseous mercury, which is quickly deposited and can potentially enter food webs in a bioavailable form. Because MDEs occur at a time when biological productivity is increasing, the interactions between pollutant transport pathways, solar radiation, and climate can be extremely important (Lindberg et al., 2002; Lu et al., 2001). It is still unclear to what extent changes in climate and pollutant pathways may affect these events (AMAP, 2002).

Anthropogenic climate change and pollution are the products of societal activity and their consequences depend heavily on human and societal conditions. The effects of pollutants on human health are determined, in part, by regulations governing the use and disposal of hazardous chemicals, policies and public health guidance regarding human intake of potentially contaminated foods, public perceptions of and responses to such guidance, how much pollutant-contaminated food people ingest, cultural attitudes toward various types of food, and what access people have to these various foods.

17.2.3. Identifying coping and adaptation strategies

The Arctic has been inhabited by many diverse groups of people for several thousand years. Each group has its own distinct history, culture, language, and economic system. Despite the cultural and economic diversity found among arctic indigenous peoples, they have, through time, adapted to a number of similar conditions, such as a challenging and highly variable environment generally unsuited for most agriculture, severe climatic conditions, extended winter darkness, changes in wildlife populations, great expanses between settlements, and sparse populations (Chapter 3). The varied livelihoods of arctic indigenous peoples are examples of such adaptation. Reindeer herding in Finnmark and Russia, and fishing, sealing, and whaling in Greenland, Canada, Russia, and Alaska reflect the ability of arctic peoples to utilize and innovate with available resources, and to anticipate environmental and social changes in ways that enable people to take advantage of opportunities and guard against adverse effects.

Colonization has been another important source of change for arctic peoples. Prior to European contact, arctic indigenous peoples lived primarily in small settlements, and those dependent on terrestrial versus marine resources led nomadic lifestyles in order to follow the animals they relied upon for their livelihoods.

Historically, their cultures, identities, social organizations, and economies centered on these livelihoods, which represent successful adaptations to local environments. More recently, however, all arctic indigenous peoples, have, to greater or lesser extent, been colonized by outsiders interested in extracting and profiting from the Arctic's resources. In addition to centuries of European and Asian settlement, arctic indigenous peoples have also encountered missionaries and traders and, more recently social, economic, environmental, and political impacts and changes brought about by globalization (Freeman, 2000). In response, many indigenous peoples have developed mixed cash–subsistence economies. Yet, despite a number of challenges, these people continue to keep alive their traditional ways of life and in recent decades have acquired considerable authority in matters of governance. Arctic peoples have shown a remarkable resilience to extreme environmental conditions and profound societal change. At the same time, cultural change could reduce the adaptive capacity of arctic peoples (Chapter 3).

Adaptive responses to environmental changes are multidimensional. They include adjustments in hunting, herding, fishing, and gathering practices as well as alterations in emotional, cultural, and spiritual life. Arctic peoples change their hunting and herding grounds, become more selective about the quality of the fish they ingest, and build new partnerships between federal governments and indigenous peoples' governments and organizations. Adaptation can involve changing personal relationships between people and the weather and new forms of language and communication developed in response to novel environmental phenomena. Changes in knowledge and uses of knowledge can also constitute forms of adaptation. Altered weather prediction techniques are an example (Chapter 3).

In this chapter the term "adaptation" is used broadly, but in some instances it requires refinement. In their discussion on the term "adaptive" Berkes and Jolly (2001) apply terminology long used in anthropology (McCay, 1997) and the development literature (Davies, 1993), to distinguish between coping mechanisms and adaptive strategies. Coping responses are the ensemble of short-term responses to potential impacts that can be successfully applied season-to-season or year-to-year as needed to protect a resource, livelihood, etc. Some forms of coping are explicitly anticipatory and take the form of, for example, insurance schemes and emergency preparedness. Adaptive responses refer to the ways individuals, households, and communities change their productive activities and modify their rules and institutions to minimize risk to their resources and livelihoods. Depending on the frequency, duration, and suddenness in the onset of a stress, and on the resilience of a system, either coping or adaptive responses or both will come into play. With a progression of change in climatic conditions, coping mechanisms may at some point be overwhelmed, and by necessity supplanted by adaptive responses.

17.2.3.1. Governance, regulations, and subsistence

A number of changes in governance and regulation are transforming arctic governments and their relationships with the rest of the world. Since the early 1970s, authority has devolved from central governments to local and regional governing bodies in places like Greenland, Alaska's North Slope Borough, and northern Quebec's Nunavik region (Young, 2000). But while indigenous peoples in these communities have gained control over local affairs, external regulations have had considerable bearing on local ways of life. Seal harvest protests in Europe and the United States have affected seal hunting livelihoods in Greenland (e.g., Hovelsrud-Broda, 1997, 1999). Recently, proposals have been made to the International Whaling Commission (IWC) to deny the aboriginal subsistence hunters in Alaska and Chukotka in Russia a quota for bowhead whales (*Balaena mysticetus*). And Sámi reindeer herders must defend their practices against claims by others that they are allowing overgrazing (Beach, 2000).

For a long time, east–west tensions and core–periphery relationships (e.g., between Greenland and Copenhagen) kept arctic relations with the rest of the world connecting, for the most part, along north–south lines. Since the 1980s, however, arctic countries have become more open to pan-arctic cooperation with, for example, the thawing of the Cold War and the growing recognition of indigenous peoples' rights (Young, 1998a). Cooperative alliances include the Arctic Council, the Inuit Circumpolar Conference, and the North Atlantic Marine Mammal Commission. The Arctic Environmental Protection Strategy (AEPS), which provided a basis for the Arctic Council, was a pan-arctic initiative begun in 1991 when the eight arctic states signed the Declaration on the Protection of the Arctic Environment. A primary purpose of AEPS was a better understanding of environmental threats through a cooperative approach to these threats (Young, 1998a). There is also an increasing effort to link arctic initiatives with global regimes such as the Convention on Biological Diversity, the UN Framework Convention on Climate Change, ozone agreements, pollution-related agreements and initiatives, and the International Labour Organisation Convention 169 concerning Indigenous and Tribal Peoples in Independent Countries (Young, 2000).

Several factors are likely to characterize arctic international relations of the future. These include a greater role for non-state actors (especially indigenous peoples and environmental groups) in arctic affairs and a focus on sustainable development as a policy goal that means different things to different people. However, the future shape of environmental institutional arrangements (e.g., geographically broad with a narrow focus on an environmental program, or geographically limited, but encompassing a wide range of environmental issues) remains to be seen (Young, 1998a).

17.2.3.2. Settlements, population, and migration

Over the past decades indigenous populations in Greenland, Finnmark, and elsewhere have tended to migrate to towns and larger settlements. These movements have generally resulted in mixed economies where individuals are more likely to engage in wage labor and supplement their cash incomes with the sale of subsistence products. While these mixed economies can perpetuate traditional systems of land use and allow the use of cash to support household hunting and fishing (Caulfield, 1997), the diets of people who migrate from smaller settlements to larger towns tend to contain significantly less marine mammal and fish (Pars, 1997).

Indigenous peoples throughout the Arctic have often coped with and adapted to change via migration. Certain types of migration, however, can pose problems. People in general have responded to changes in animal populations and movements by altering their own locations and movement patterns and by varying the types of species hunted. Migration to towns might also serve as an adaptive strategy if, for example, economic trends, regulations and/or the effects of climate change and pollution make hunting or fishing in settlements impractical or unproductive. The movement of Greenlanders to permanent towns and settlements over recent decades restricted the ability of hunters to follow animals on their seasonal migrations, introduced more Greenlanders to wage labor, and helped to catalyze the indigenous political movement that culminated in Home Rule. Alternatively, certain economic conditions, regulatory policies, and/or the stresses of urban life could conceivably prompt people to move from towns to settlements. This type of coping through mobility is evident in Greenland over the past thirty years as the size, composition, and distribution of Greenland's population during this period has varied with changes in policies, economics, and educational and occupational opportunities.

Migration and settlement practices have also had implications for governance. Danish government policy encouraging a growth in town populations led many Greenlanders to concentrate in towns and major settlements in the 1960s. Migration from rural to more urban areas was part of Danish modernization programs of the 1950s and 1960s. These programs, for example, shut down a number of small settlements so that their inhabitants could work in fish-processing plants located in larger towns. Many Greenlanders were not in favor of these activities, believing that they were detrimental to Greenlandic culture and practices. Greenlandic resistance to forced migrations and other modernization initiatives eventually contributed to the establishment of Home Rule (Caulfield, 2000).

17.2.3.3. Consumption

Access to new foods and technologies have accompanied changes in diet and livelihood practices, respectively, and mark important ways in which consumption patterns are

part of changing arctic lifestyles. The diets of indigenous peoples are changing as they use smaller amounts of traditional foods, and rely more on commercially available products and imports. These changes have implications for culture and health as traditional foods are closely tied to indigenous identity and offer significant nutritional benefits (Kuhnlein and Chan, 2000). A decrease in traditional foods combined with an increase in western foods in the diet of indigenous peoples increases the rate of western diseases such as heart disease. Examples of technological change include snowmobile use which has accompanied changes in transportation, hunting, trapping and fishing, and recreation and tourism among the Sámi in Norway (Muga, 1987). In addition, imported modern hunting equipment has made whaling and marine mammal hunting activities, in general, safer and more efficient in Alaska, Greenland, and Canada.

17.2.3.4. Economies, markets, and trade

Mixed economies based on wage labor and on subsistence activities are increasingly prevalent in arctic indigenous communities (Chapter 3) and broader trade and growing access to markets have innumerable implications for arctic indigenous peoples. Easier access to world markets continues to provide arctic inhabitants with increasingly better access to new material goods and new sources of income. At the same time, growing arctic-based businesses (e.g., tourism, see Chapter 12) can be sensitive to fluctuations in the distant economies to which they connect. An important question is whether, and if so how, this type of economic diversification affects resilience of local household and community economies.

17.2.3.5. Connectivity

A particular way in which technology is part of transformations in the Arctic is via the provision of new means of communication such as television, Internet, and telephones. The Anik satellites in Canada, for example, have been instrumental in exposing Inuit to outside cultures and in providing these peoples with a tool for asserting their own identity and culture (Stenbaek, 1987).

17.3. Methods and models for vulnerability analysis

A successful vulnerability assessment is one that prepares specific communities for the effects of likely future change. A vulnerability assessment should: draw upon a varied and flexible knowledge base; focus on a "place-based" study area; address multiple and interacting stresses; allow for differential adaptive capacity; and be both prospective and historical (Polsky et al., 2003). Data and methodologies to support such an assessment vary widely and any given vulnerability study is likely to involve a variety of quantitative and qualitative forms of data and methodological techniques. Interviews with "key informants" and surveys (Kelly and Adger, 2000) have been employed to obtain data on transience, immigration and education levels, income, education, age,

family structure (Clark et al., 1998), literacy, infant mortality, and life expectancy (Downing et al., 2001). Floodplain maps are important in analyzing the vulnerability of communities to extreme storm events (Clark et al., 1998). Agricultural vulnerability analyses often require information about extent of land degradation, crop type, soil moisture, runoff, and groundwater (Downing et al., 2001). As described by Cutter (1996) analytical techniques can include historical narratives, contextual analyses, case studies, statistical analyses and GIS approaches, mapping, factor analysis and data envelopment analysis, and vulnerability index development (see also Downing et al., 2001). Thus, what is novel about vulnerability assessments is not the individual techniques used to explore specific parts of a coupled human–environment system, but the integration of these techniques across varied intellectual domains.

A framework, such as that proposed by Turner et al. (2003a) enables at least two approaches for investigating vulnerability (see Fig. 17.1). One approach is to begin with knowledge about stresses and trace them through to consequences, while another is to begin with consequences and trace these back to stresses. It is also possible to work in both directions in an iterative fashion to yield a more comprehensive analysis. Figure 17.4 presents a research approach that allows for iterative analysis, in which (reading from left to right) information about stresses and their interactions are used both to develop scenarios and to project impacts. Impact projections can be used in conjunction with interviews, focus groups, workshops, and other means for engaging residents of the place of interest to explore coping strategies and adaptive capacities of a human–environment system. Knowledge of impacts and adaptive capacity can then be used to characterize site-specific vulnerabilities. Proceeding from consequences to stresses (right to left), researchers can work with residents of a particular locale to identify consequences experienced within a coupled human–environment system and then trace them back to identify the specific nature of the stresses.

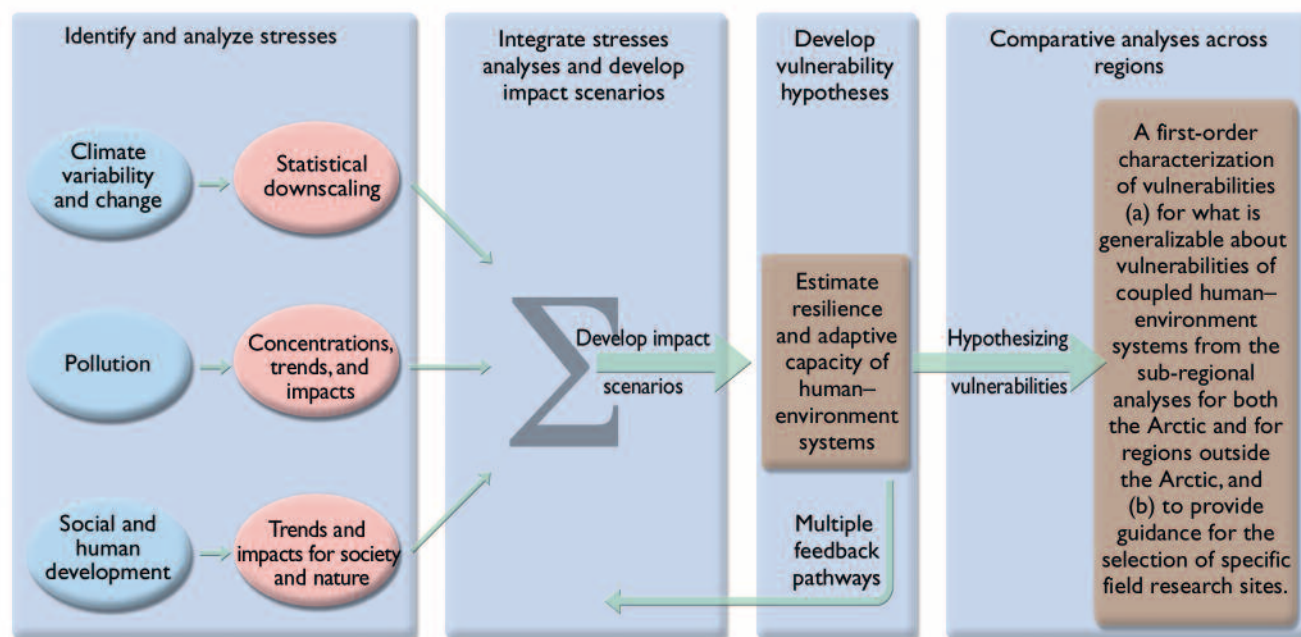
Application of a framework to understand vulnerabilities within a coupled human–environment system requires different types of knowledge, as well as tools from a wide range of disciplines and from local and indigenous sources. For example, vulnerability analysis in the form presented here requires integration of natural science, social science, indigenous and local knowledge, cooperation among researchers and people who are part of the coupled human–environment system under study, and reliance on diverse techniques such as interviews, participant observation, focus groups, climate modeling, and climate downscaling. A proper vulnerability analysis will engage (1) a number of scientific disciplines (ecology, biology, climate and global change research, meteorology, social anthropology, sociology, political and policy science, economics, geography, ocean sciences, physiology and veterinary science, and environmental chemistry) and (2) local people with significant knowledge of their environment, of relevant


Fig. 17.4. Methodological framework.

social, political, and economic factors, and of human–environment interactions concerning, for example, hunting, herding, gathering, processing, and production. The success of a vulnerability assessment depends on the success of partnerships among various groups of stakeholders (Polsky et al., 2003).

17.3.1. Climate scenarios and downscaling to specific sites

An active area of climate change research is the translation of atmosphere–ocean general circulation model (AOGCM) projections calculated at large spatial scales to smaller spatial scales, a process termed "downscaling". In this way, selected study sites can be provided with customized climate projections. There are two principal approaches for downscaling: dynamical downscaling (also known as regional climate models) and statistical downscaling (also known as empirical downscaling). As described in Chapter 4, there are advantages and disadvantages to each approach. While both generate similar results for current climate, they have been known to generate different projections for future climates.

Greenhouse gas emissions scenarios used to drive the AOGCMs are based on projections of economic activity. In turn, the projected economic activity is a function of anticipated changes in global population, technology, and trends in international trade. As a result, each of the 40 scenarios used by the IPCC can be characterized by its anticipated trajectories of population, economy, environment, equity, technology, and globalization (IPCC, 2001a). It is impossible to assign likelihoods to these or any other GHG emissions scenario. Thus the IPCC emissions scenarios are individually equally plausible, but collectively represent only a subset of the possible futures.

Current arctic climate projections are limited in their utility for vulnerability analyses for two main reasons. First, the AOGCMs that produce these projections do not capture all important features of regional climate. For example, local ocean and atmospheric circulation patterns, and topographic relief are not well represented in AOGCMs. These factors often play a decisive role in determining local climate in the Arctic. As a result, additional analytical techniques are needed to produce local-scale climate projections. Chapter 4 reviews the various methods available for this task.

Second, for downscaling results to contribute to successful vulnerability assessments, local people must be involved in the planning and analysis of downscaling studies (Polsky et al., 2003). Otherwise, the downscaled climate projections may not reflect the climate factors relevant for decision-making to enable arctic residents to adapt or employ mitigation strategies. For example, one of the climate variables of concern for reindeer herders in northern Norway is snow quality. Too much snow hinders reindeer mobility and restricts their access to food on the ground, especially when the snow contains enough ice to mask the smell of the food. Too little snow, by contrast, makes it difficult for the herders to contain the reindeer (no restrictions on mobility) and to track the animals when they stray (no snow tracks). For these and other reasons, the Sámi employ many words to describe snow quality, as it relates to timing, amount, consistency, bearing, surface, trees, thawing, patches, accessibility, and other aspects (Ruong, 1967). The point here is that the way climate matters for any particular activity is specific to that activity. Thus a downscaled projection of, for example, mean monthly surface temperature may not be sufficient (or even necessary) information for contributing to the process of social adaptation to the effects of climate change for any group of arctic people.

Likelihoods of extreme conditions are difficult attributes to derive with confidence from climate scenarios, especially at the local scale, and this is the scale of most interest in assessing vulnerabilities in human–environment systems. As Smithers and Smit (1997) pointed out, "frequency, duration, and suddenness" of climatic events influence the character of successful adaptation strategies. Higher frequency of a potentially harmful event will heighten decision-makers' awareness of risk associated with a class of climate events. Greater duration of a climate event could inflict a correspondingly greater impact, or alternatively allow for more adaptation than would be possible with a shorter duration but otherwise similar event. Rapid onset of a particular climate event or condition, whether a specific flood or myriad aspects of the broader syndrome of climate change, will be much more limiting with respect to adaptation options than slowly rising water or very gradual climate change. Scales of social and political organization are important, since they reflect inertia in the response or adaptive capabilities of a human–environment system (Berkes and Jolly, 2001). Future projections of arctic climate change models (see Chapter 4) do not yet systematically resolve details in climate extremes that will be useful for assessing changes in frequency, duration, and suddenness of most climate events. Within the last few years, however, some progress has been made with ensemble simulations, especially for precipitation (Palmer and Räisänen, 2002).

17.3.2. Measurement and methodology for pollutant analyses

Data on POPs and heavy metal pollution and impacts for many arctic locations are now available. Although analytical methodology has advanced significantly for both since the late 1970s, some older and more recent data can be difficult to compare. For example, early PCB studies reported concentrations relative to industrial mixtures (e.g., Aroclor). Current studies report PCBs as a sum of individual congeners. In addition, levels of POPs and metals in biota may differ dramatically depending on the species sampled, the part of the individual animal from which the sample was taken, and the age and sex of the sampled individual. Shifts in diet can also affect exposure. Few studies have monitored the same species at the same site over a long timescale, a procedure necessary for making reliable comments on trends. Heavy metals pose an additional challenge for measurement and assessment because they are derived from both anthropogenic and natural sources. It is not always possible to determine whether a given concentration measured in biota originated from a natural or an anthropogenic source (Muir et al., 1999). In the last few years, the assessment and standardization efforts implemented by AMAP have dramatically improved knowledge of the pollutant situation in the Arctic. The data used here for analyzing interactions with multiple stresses and for identifying vulnerabilities draw heavily on the latest AMAP assessment (AMAP, 2002).

17.3.3. Analysis of human and societal trends

Data on trends in human and societal conditions can be obtained from published and unpublished institutional and governmental databases (e.g., Statistics Greenland) and from research in fields such as anthropology, sociology, political science, economics, and native studies. An in-depth analysis of human and societal trends requires a wide array of data sources, extensive statistical analysis, and knowledge shared and generated through interactions between researchers and arctic residents. Such an analysis might draw upon economic data pertaining to markets operating at various scales, employment, retail transactions, trade, imports, exports, and the processing and sale of natural and other resources. Public health information can also form an important part of human and societal trends analyses with information about contaminant levels in food and humans, diseases, and health care. Census data can provide information about general demographics, education, family structure, employment, and migration patterns. Election data can be useful in revealing trends in governance and the implementation and enforcement of regulations and policies emanating from transnational, national, and subnational decision-making bodies. Archives and other documentation that track negotiations and participation within such bodies are also useful. Surveys and interviews with local people are essential in ascertaining the views of individuals with, for example, respect to dietary practices, consumption patterns, values, and priorities.

17.3.4. Sources of local knowledge and stakeholders as participants

The vulnerability of a coupled human–environment system will be perceived differently across cultures, age groups, economic sectors, etc. A reindeer herder will most likely define the vulnerability of his/her human–environment system differently than would an outsider assessing the same system. There may also be diverging opinions within a community. There may well be a range of different perspectives on what constitutes a vulnerable condition and it is essential to recognize and address these perspectives in carrying out a vulnerability analysis. Evaluation of the exposure, sensitivity, and adaptive capacity of a coupled human–environment system will require the knowledge, observation, and participation of people who are part of the system. These people can, for example, identify important stresses, human–environment interactions, and outcomes that they seek to avoid. They can also identify changes in the human–environment system, describe coping and adaptive capacities, monitor environmental and social phenomena, and communicate research findings. The involvement of local people in research design, implementation, and the dissemination of research results should, therefore, be a central aspect of any comprehensive vulnerability study.

Participatory research has become increasingly common in arctic research on socio-ecological changes, as evident

throughout this assessment and a number of other projects e.g., SnowChange (Mustonen, 2002), Scannet (Scannet, no date), the Mackenzie Basin Impact Study (Cohen, 1997), Voices from the Bay (McDonald et al., 1997), and Inuit Observations on Climate Change (IISD, 2001). Participatory research follows from a long tradition. From the time people in the "South" began to take an interest in the high latitudes, indigenous peoples of northern regions have often had a role to play in arctic research and exploration. Early anthropologists and archaeologists frequently used indigenous peoples as guides, laborers, informants, and/or interpreters (e.g., Boas, 1888; Rasmussen, 1908; Stefansson, 1941), as did arctic seamen and explorers (Peary, 1907). Since those days, indigenous peoples have continued to work with visiting researchers and explorers. Throughout, there have been a variety of reports on the positive and negative outcomes of these interactions and relationships (e.g., Harbsmeier, 2002). However, despite the many ways in which arctic indigenous peoples have contributed to arctic research, often there has been little mention of their role or acknowledgement of their efforts (Brewster, 1997).

The way outside researchers worked with indigenous peoples changed considerably in the mid-1980s. Coinciding with the settlement of land claims, the emergence of co-management regimes, and the ascendancy of indigenous peoples' power and influence in formal decision-making processes (Kuhn and Duerden, 1996), indigenous knowledge became a topic of interest for many researchers who worked in the Arctic. It was centered around a few key themes: documentation of indigenous knowledge about various aspects of the environment (Ferguson and Messier, 1997; Fox, 2004; Huntington and the communities of Buckland, 1999; Jolly et al., 2003; Kilabuck, 1998; McDonald et al., 1997; Mymrin and the communities of Novoe Chaplino, 1999; Reidlinger and Berkes, 2001); the increasing use of cooperative approaches to wildlife and environmental management (Berkes, 1998, 1999; Freeman and Carbyn, 1988; Huntington, 1992; Pinkerton, 1989; Usher, 2000); environmental impact assessment (Stevenson, 1996a); and collaborative research between scientists and indigenous peoples (Huntington, 2000; Krupnik and Jolly, 2002). This last theme has particular relevance for vulnerability studies. A brief literature review on the development of collaborative and participatory research in the Arctic follows.

Early efforts to involve arctic indigenous peoples in research and land management began with much discussion on the validity and utility of indigenous knowledge. Researchers who had worked with indigenous peoples for some time recognized that indigenous knowledge could reveal valuable information that could augment scientific understanding about many aspects of environment and ecology. Further, some researchers were beginning to recognize that indigenous knowledge holders needed to participate in the research process themselves (e.g., Wenzel, 1984). Seminal edited volumes on northern indigenous knowledge, e.g., Johnson M. (1992) and Inglis (1993) use case studies from the Arctic to present a number of perspectives on the validity and utility of this knowledge. The case studies illustrate that indigenous knowledge can make a key contribution to resource management and sustainability. Arguing for the inclusion of indigenous peoples in research and decision making, several case studies present examples of how these initiatives were needed, or underway, in a variety of settings. For example Eythorsson (1993) explained why the knowledge of Sámi fishermen in northern Norway is integral to successful resource management there and Usher (1993) discussed some of the successes of the Beverly-Kaminuriak Caribou Management Board, one of the earliest examples of wildlife co-management in North America.

As interest in indigenous knowledge in the Arctic picked up through the 1990s, many people continued to focus on promoting the validity and utility of indigenous knowledge and the need to integrate it into research and management. However, critiques began to surface that questioned the methods behind the "integration", as well as the intentions. Bielawski (1996) examined interactions between scientists and indigenous land users involved in co-management systems and noted that, although co-management is supposed to combine scientific and indigenous expertise, the model and process for co-management is not integrative at all, but scientific and bureaucratic. Usher (2000) echoed this when stating that although indigenous knowledge (also called TEK, "traditional ecological knowledge") is required to be incorporated into Canadian resource management and environmental assessments there is little understanding of what TEK is and how to implement it in policy. This confusion was especially visible during 1996 when a senior policy advisor with the Northwest Territories (NWT) government wrote an article claiming that the inclusion of indigenous knowledge in environmental assessments not only hinders the scientific process, but is against the constitutional rights of Canadian citizens since indigenous knowledge is based on spiritual beliefs, not facts (Howard and Widdowson, 1996). The article created a heated debate (see Berkes and Henley, 1997; Stevenson, 1996b) and caused both researchers and managers to look more closely at the reasons and methods for incorporating indigenous knowledge into research and policy. As shown by Usher (2000), these reasons and methods remained unclear until the end of the 1990s. In 1999, others such as Nadasdy (1999) still believed that indigenous knowledge and the engagement of indigenous peoples in research were not taken seriously and were merely paid lip-service for political reasons. Nadasdy (2003) called for a more critical look at "successful" co-management efforts and the political, as well as methodological obstacles, to the integration of indigenous knowledge.

By 2000, a number of indigenous knowledge projects in the Canadian Arctic and Alaska had made advances in participatory methods for working with arctic communities (Krupnik and Jolly, 2002). For example the Tuktu (caribou) and Nogak (calves) Project (Thorpe et al.,

2001, 2002), which documented Inuit knowledge of Bathurst caribou and calving grounds in the Kitikmeot region of Nunavut from 1996 to 2001, established a local advisory board for the project and relied on trained local researchers to help with interviews and data analysis. Fox (1998, 2004), who has a long-term project with Nunavut communities regarding Inuit knowledge of climate and environmental change, has used an iterative approach to community work, incorporating community input and feedback in research methods. Jolly et al. (2002) also used an iterative approach over a one-year project in Sachs Harbour, NWT to collect Inuvialuit observations of climate change. In the Sachs Harbour project, scientific experts worked one-on-one with local experts to understand a variety of phenomena and community workshops were held to establish common goals for the research and to clarify information. A number of other projects and management systems have incorporated participatory approaches with much success in recent years (Huntington, 1998, 2000; Kofinas and the communities of Aklavik, 2002; Krupnik and Jolly, 2002). Common to many of these projects are some aspects of participatory research in the Arctic that have emerged as key including time, trust, communication, and meaningful goals and results. Many of these projects span multiple years, where researchers and community members form friendships and fruitful working relationships. In several projects, results were produced in forms that the community could use and found interesting. For example, the Tuktu and Nogak Project produced a community-directed book (Thorpe et al., 2001). Fox (2003) developed an interactive multi-media CD ROM and an Inuktitut book for participants, and the Sachs Harbour project created a documentary film (IISD, 2000).

Indigenous peoples themselves are also making an impact on participatory research in the Arctic. Many arctic communities and organizations are reaching out to scientists and decision-makers to set research priorities and form partnerships for investigations (Fenge, 2001).

17.4. Understanding and assessing vulnerabilities through case studies

Comparative vulnerability assessments at continental scales (IPCC, 2001b) can reveal regional differences in the vulnerability of human–environment systems. The differences reflect, for example, geographically uneven rates of climate change projected in regional climate scenarios and broad regional distinctions in the capacity of individuals and institutions to cope with and adapt to change.

The Third Scientific Assessment of the IPCC ascertained the following as likely projections for the Arctic using the IPCC scenarios for climate change (Anisimov and Fitzharris, 2001):

> *The Arctic is extremely vulnerable to climate change, and major ecological, sociological, and economic impacts are expected.*

> *Habitat loss [will occur] for some species, and apex consumers — with their low-reproductive outputs — are vulnerable to changes in the long polar marine food chains.*

> *Adaptation to climate change in natural polar ecosystems is likely to occur through migration and changing species assemblages but the details of these effects are unknown.*

> *Loss of sea-ice in the Arctic will provide increased opportunities for new sea routes, fishing and new settlements, but also for wider dispersal of pollutants.*

> *Although most indigenous peoples are highly resilient, the combined impacts of climate change and globalization create new and unexpected challenges. Because their livelihood and economy increasingly are tied to distant markets, they will be affected not only by climate change in the Arctic but also by other changes elsewhere. Local adjustments in harvest strategies and in allocation of labor and capital will be necessary. Perhaps the greatest threat of all is to maintenance of self-esteem, social cohesion, and cultural identity of communities.*

This chapter builds upon more general climate change vulnerability analyses by placing climate in the context of other factors that can enhance or diminish vulnerability of arctic systems to future climate change. In order to ensure that such an analysis realistically characterizes the perspectives of the people who will be making decisions to apply coping and adaptive strategies to increase resilience, and hence minimize vulnerability, a vulnerability analysis must focus on a particular place. The dynamic character of vulnerability requires that the human–environment system be represented on a scale that is meaningful to individual decision-makers.

Sections 17.4.1.1 and 17.4.1.2 provide examples for which a vulnerability assessment would be tractable, revealing, and ultimately useful to residents of the Arctic who will be making decisions in relation to future change. The first example (see section 17.4.1.1) is drawn from a case study on the Sachs Harbour community, NWT, Canada. This case study is one of several such cases presented in Chapters 3, 11, and 12 for which a vulnerability analysis would be illuminating. The study of Sachs Harbour, however, is particularly well suited because its design and development fully engaged the residents of this community, while detailing the ways in which local people and other stakeholders view, experience, and respond to climate change. The community has a mixed economy, with strong historical dependence on fish and wildlife, and lies in a region of the Arctic that experiences high rates of climate change. However, at this time it is not possible to go beyond the work that has already been conducted with respect to recent and likely future climate change. Without a new phase of research that fully involves the Inuvialuit people of Sachs Harbour, their resilience in accommodating interactive future impacts of changes in climate and other stressors cannot be assessed. A

primary purpose of the description in section 17.4.1.1 is to signal the importance of the next phase in such an assessment in this community.

The second example (see section 17.4.1.2) focuses on the coastal communities of Greenland. These communities are attractive potential sites for vulnerability analysis because of their historical documentation of their strong dependence on marine living resource use, including fishing, sealing, and whaling for subsistence and income, and in particular their growing knowledge of the amounts of pollutants in the local marine food webs. In addition the governance of Greenland is evolving, and its institutions will continue to play important roles in shaping coping and adaptive capacities for Greenlanders. Research on this human–environment system is at a very early stage. In order to proceed, residents knowledgeable about the roles of past and likely future climate in local livelihood activities must be engaged.

Furthermore, assessing climate change in the context of multiple stresses and resilience in both Sachs Harbour and coastal Greenland will require scenarios, i.e., a range of plausible futures. These scenarios should reflect the combined effects of likely future changes in climate, in other environmental factors that could affect livelihoods (e.g., natural resources), and in human and societal conditions that influence resilience and coping strategies.

A third example (see section 17.4.2) focuses on reindeer populations and reindeer herding in Finnmark, Norway. Reindeer herding by Sámi takes place well inland in winter and on the coast and nearby islands in summer. This practice involves management of grazing grounds in both locations and migration of the herds between them in spring and autumn. The long history of these practices during periods of past climate change and the increasing role of governmental regulation raises interesting questions about the vulnerability of this system. Sámi reindeer herding represents a tightly coupled human–environment system in which indigenous peoples interact closely with an ecosystem upon which they depend for their way of life.

Two additional factors support the inclusion of the Finnmark case study. A vulnerability assessment has recently been conducted for Norway (O'Brien et al., 2004). It aptly demonstrates that the arctic region of Norway will be more vulnerable to climate change than more southern regions, and the importance of selecting the appropriate scale of analysis in vulnerability assessments. Secondly, work to date with the Sámi reindeer herding community in Finnmark offers an excellent example of the co-generation of knowledge involving academic scientists and indigenous peoples. A research effort is now underway to ascertain the resilience of this system to future change in climate and other factors, and the preliminary findings from this study are discussed below.

These three communities and livelihoods are not intended to be representative of the Arctic as a whole. They have been selected because they present examples of tightly coupled human–environment systems in which indigenous peoples interact closely with local ecosystems and rely upon these ecosystems to support their ways of life. Yet, they also span different geographic settings, environmental conditions, governance systems, and socio-ecological dynamics. For example, neither Sámi reindeer herders nor reindeer herding itself are "typical" of anything beyond themselves. The system of which they form a part possesses unique ecological, sociological, and ethnological features. Therefore, the system represents a useful site in which to examine the plasticity and adaptability of a generalized methodological framework for vulnerability studies.

In each of these cases there lies potential to test concepts and methodologies described in this chapter and to present information about stresses, sensitivity, and resilience within the coupled human–environment system. Other examples could have been developed by building upon material presented in Chapters 3 and 12. For example, the Dene Nation, NWT, Canada, and the Yamal Nenets of Northwest Siberia. The Dene case study (Chapter 3) is of interest because of the success of the Dene in forming the Denendeh Environmental Working Group. The Dene culture emphasizes interconnectedness among all aspects of the environment, and this working group is observing, documenting, and communicating information related to climate change. However, there is not much information available to judge what factors in addition to climate change are contributing to the vulnerability and resilience of the Dene at this time, and the detailed content of their working group reports are not yet publicly available. The Yamal Nenets case study (Chapter 12) is of interest because it focuses, like the Finnmark study, on a reindeer herding livelihood with a history of adaptive management during times of change. The Yamal Nenet situation differs from that of the Finnmark herders in that the Yamal Nenets are experiencing stresses relating to oil and gas extraction, and might in the future experience stresses related to Northern Sea Route coastal development made possible by climate change. Krupnik (2000) and Krupnik and Jolly (2002) suggest that these other stresses may be straining the resilience of a livelihood that has sustained Nenet people for centuries. Although a comparative analysis of the Yamal and the Finnmark cases would certainly be instructive it is premature given the preliminary character of research on each of these at this time.

17.4.1. Candidate vulnerability case studies

The following are preliminary findings from the two sites for which assessments of climate change in the context of multiple stresses and resilience would be particularly timely. Knowledge about what makes a system either vulnerable to or resilient to change can be used to minimize risks and damage and to capitalize on opportunities. Regional scenarios for climate and other changes and field research conducted with the full participation of inhabitants of Sachs Harbour and coastal Greenland

will be needed to develop an assessment of climate impacts and other changes beyond these initial findings.

17.4.1.1. Sachs Harbour

Berkes and Jolly (2001) have identified three reasons why the Arctic is a highly appropriate region in which to address questions relating to human adaptations to climate change. First, people living in the Arctic, particularly indigenous peoples with subsistence livelihoods, have historically experienced a high degree of climate variability, and their ability to adapt to varying climate, from seasonal to interannual, is part of their culture. Second, as is well documented in earlier chapters, the rate of climate change recently experienced in the Arctic, and likely to continue over the next several decades, may be exceeding the range of experience and hence capacity of arctic peoples to adapt. Third, there is a growing body of participatory research, with topics ranging from wildlife co-management to the use of traditional knowledge in environmental assessments (Berkes et al., 2001). The focus of the analysis by Berkes and Jolly (2001) is a Canadian Arctic community, Sachs Harbour, on Banks Island, NWT.

Sachs Harbour, a community of 150 Inuvialuit hunters and trappers was the subject of a two-year study (1999–2001) by the Canadian International Institute for Sustainable Development (Ashford and Castledown, 2001). This area is known to have been inhabited episodically, beginning with Pre-Dorset peoples over 3500 years ago. Traditional livelihoods (hunting, trapping, fishing) continue to thrive, and increasingly tourism, including guiding and the sale of arts and crafts, contributes to the local economy. The study became widely known through the distribution of an educational video, and several research papers (Ford, 2000; Fox et al., 2001; Riedlinger, 2000).

The report on this study describes a community at a crossroads. Climate has changed in recent decades and traditional ways of predicting weather are no longer reliable. Within the last few decades the later dates for autumn freeze-up, earlier dates for spring thaw, thinner winter ice, diminished extent of multi-year sea ice, thawing permafrost, and increased coastal erosion have altered abundances of and accessibility to fish and wildlife. The people of Sachs Harbour wonder whether they can maintain their traditional ways of life if these trends continue.

Berkes and Jolly (2001) analyzed the adaptive capacity of this community, considering a continuum of near-term coping responses to longer term cultural and ecological adaptations. Given the high degree of natural climate variability in the Arctic, coping strategies have always been essential for the success of indigenous peoples' livelihoods. These strategies include adjusting the timing of activities and switching between fished and hunted species to minimize risk and uncertainty in harvest. Waiting is also a coping strategy. "People wait for the

geese to arrive, for the land to dry, for the weather to improve, or for the rain to end". But as annual climate cycles become more and more unfamiliar, new strategies are necessary. With changes in snow and ice cover, permafrost conditions, and coastal erosion, modes of transportation need to change. Greater unpredictability in weather also requires a greater caution for those who travel on ice. Coping with changes in harvest has in some regards become easier as alternatives to traditional diets have become more available with the growing reach of market economies.

Longer term adaptive responses that are considered central to the long-term success of indigenous peoples in the Arctic are categorized as follows: (1) mobility and flexibility in terms of group size; (2) flexibility with regard to seasonal cycles of harvest and resource use, backed up by oral traditions to provide group memory; (3) detailed local environmental knowledge and related skill sets; (4) sharing mechanisms and social networks to provide mutual support and minimize risks; and (5) intercommunity trade (Berkes and Jolly, 2001). The authors go on to suggest that the first response, mobility and group size, became much less relevant following the settlement of Inuit in permanent villages several decades ago. However, the remaining four responses have continuing potential to offer some adaptive capacity to deal with future climate change.

But will these time-proven strategies be sufficient for a future where factors in addition to climate change become increasingly important in this human–environment system? Are there other adaptive responses that need to be examined? Increasing dependence on cash economies and industries such as tourism raise new questions about the sustainability and overall vulnerability of this system.

The co-generation of knowledge in the IISD study, which fully involved the Inuvialuit people of Sachs Harbour, sets the stage for discussions about vulnerabilities in this location. However, in addition to participatory research methods to support the collaboration of researchers and local peoples, there are also institutional arrangements in this region that can facilitate the assessment of vulnerability in the context of multiple stresses, including climate change, pollution, and economic change. Over the last two decades co-management bodies have arisen that provide individual Inuit communities with formal mechanisms to interact with regional, territorial, and federal government institutions. These bodies provide greater local flexibility and response capacity in dealing with local uncertainties such as climate change (Berkes and Jolly, 2001). Moreover, they facilitate self-organization and learning across levels of organization, thus enhancing feedbacks across the levels. A community like Sachs Harbour can improve its understanding of risks and vulnerabilities and therefore better prepare itself for the future by examining possible effects of and responses to climate change in a historical perspective and within the context of other forms of social and environmental transformation.

17.4.1.2. Greenland

Communities in Greenland (and other similar communities elsewhere in the Arctic) that rely heavily on living natural resources, such as marine resources, might utilize vulnerability analysis in anticipating and planning for future social and environmental changes. Many such communities have a mixed subsistence/cash economy that involves a combination of commercial fishing, wage employment, and small-scale hunting and fishing activities. Commercial fishing (for shrimp, Greenland halibut (*Reinhardtius hippoglossoides*) and other species) is dominant in terms of monetary return. The residents of these communities and the environments with which they interact are affected by many factors including governance and market dynamics spanning local to global contexts, as well as climate and pollution. Recent decades have witnessed significant changes in these variables and the future may hold even more pronounced alterations. A vulnerability analysis could be useful for residents, other stakeholders, and decision-makers in identifying which social and environmental influences warrant their concern, the potentially advantageous or adverse consequences of these factors, and how human–environment systems could respond.

Climate change could have important consequences for Greenland's human–environment systems. Recent statistically downscaled temperature scenario results based on the Max Planck Institute climate model ECHAM4/OPYC3 for Greenland project a warming trend for the period 1990 to 2050 of 1.3 to 1.6 °C for West Greenland and around 0.4 °C for East Greenland (Førland et al., 2004). In West Greenland such a trend is likely to have significant implications for sea-ice cover, for ice-dependent marine mammal species such as the ringed seal, and for hunting and fishing activities that require secure ice cover.

Pollution is another factor that could bear on the vulnerability and resilience of Greenland's human–environment systems. Although no clear effects on human health are presently observed in Greenland, the occurrence of POPs and heavy metals in traditional foods is identified by some researchers as an important environmental threat to human health (AMAP, 2003; Bjerregaard, 1995). Health concerns have been expressed in particular for pregnant women and small children (AMAP, 2003). Greenlandic residents have in general a high consumption of marine mammals and fish and are exposed to POPs mainly through their marine diet. Data indicate that levels of some POPs in biota in Greenland have decreased over the past 20 years, although it is difficult to compare earlier and more recent data for methodological reasons (Frombert et al., 1999). Given international and national policies regarding these compounds, it is reasonable to expect that environmental levels of DDT, PCBs, and HCH in Greenland will decline toward 2020 (Macdonald et al., 2003). In contrast, PBDE levels are increasing in some parts of the Arctic (AMAP, 2002).

Data since the mid-1990s reveal that the estimated average human intake of both Hg and Cd from local marine food continues to greatly exceed the FAO/WHO limits (Johansen et al., 2000). The study that produced these data involved surveys in two towns and two settlements in the Disko Bay region where the main dietary source of Hg and Cd was seal liver. This study shows that Hg and Cd are still posing problems in arctic ecosystems and could affect humans whose diet results in high levels of exposure to these metals. Most Hg contamination arises from long-range transport and there are indications of increased Hg levels in seabirds and marine mammals in West Greenland (AMAP, 2002). Smoking is often the major source of human Cd contamination. Lead contamination, another heavy metal of concern in the Arctic, is linked to the use of lead shot for bird hunting (Johansen et al., 2001) and to continued use of leaded gasoline in parts of Russia and in some non-arctic countries.

Governance could shape the vulnerability and resilience of human–environment systems in marine resource use communities. The distribution of power among supranational, national, and sub-national decision-making bodies, for example, could help to create or ameliorate particular problems for a given human–environment system and could influence the ability of such a system to anticipate and react to stresses or potential stresses. Self-determination and self-government via Home Rule (established in 1979) allow Greenlanders a greater say in charting the country's economic and social development. However, some observers argue that the Greenlandic government, though supported by Greenland's inhabitants, has allowed for less autonomy at local levels than did its predecessor. According to this view, local people had more control over access to territory and other aspects of natural resource use and management under the more distant central government (Dahl, 2000). Currently, hunting methods and catches of a number of target species are influenced to a large extent by scientific data and by the management institutions that draft hunting and fishing regulations. Prior to the early 1990s, local communities granted territorial access for hunting and fishing to all members of a local community. This access (e.g., available for full-time hunters and fishers and fishing vessel owners) is now decided by the centralized Home Rule Government that manages hunting and fishing through regulations.

Natural resource management decisions are further influenced by international laws and policies and global markets. Greenland is heavily involved with transnational policymaking that has implications for domestic governance decisions regarding natural resource use and the environment. Consequently, Greenlandic hunters and fishers have to cope with and adapt to international politics and policymaking concerning species conservation and other matters. Greenland is represented in several multilateral fishery organizations and Greenland and the EU renegotiate a fishing agreement every five years (Nuttall, 2000; Statistics Greenland, 1997). The Home

Rule Government sets fishery quotas based on recommendations of biologists and international organizations (Statistics Greenland, 1997). In addition, global competition among commercial fisheries forces Royal Greenland (an independent limited company owned by the Home Rule Government that engages in the catching, processing, manufacture, and distribution of seafood products) to fish more efficiently (so affecting the nature of the fishery) and to cut costs (which can include shutting long-operating processing plants in some communities). This situation has important implications for households that engage in the fishing industry and rely to varying degrees on subsistence hunting and fishing.

Whaling of minke (*Balaenoptera acutorostrata*) and fin whales (*B. physalus*) in Greenland is subject to a variety of political pressures and regulations. Whales caught for subsistence purposes are to be used only for local consumption and may not be exported. The Greenland parliament regulates minke and fin whaling by, in part, requiring that whalers have a full-time hunting license, reside in Greenland, and have a "close affiliation" with Greenlandic society, a special whaling permit issued for each whale taken, and, at minimum, a 50 mm harpoon canon with a penthrite grenade (if a fishing vessel is used, the harpoon canon offers the best method for killing the animal). The Home Rule Government, in conjunction with the national hunters and fishers association (KNAPK) and the nationwide municipal government organization (KANUKOKA), allocates IWC quotas for minke and fin whales. After a municipality receives its annual quota consultations take place with the local hunter and fisher associations and quotas are assigned to vessels and collective hunters (Caulfield, 1994).

Marine mammal hunters have been subject to international protests and bans on marine mammal products since the early 1980s. The EU has maintained its 1983 trade ban on sealskins for certain species of seal pups, the 1972 Marine Mammal Protection Act remains in place, and the International Convention for the Regulation of Whaling (and its Commission – the IWC), sets quotas for aboriginal subsistence whaling. In addition, environmental and animal welfare organizations (e.g., Greenpeace, the International Fund for Animal Welfare, and the World Wildlife Fund) continue to criticize and protest against marine mammal utilization. Indigenous arctic peoples argue against restrictions on marine mammal hunting on the basis that the targeted animals are not endangered and that protests are not based on science, but on ethics particular to industrialized country politics (Caulfield, 2000).

Commercial and non-commercial fishing and hunting practices are inextricably linked and are integral to the social, economic, and cultural lives of Greenlanders. Marine resource use in general, entails cultural and social organization on many levels, through shared language, transmission of appropriate behavior, validation of identity, and reinforcement of social ties and kinship networks. Sealing and whaling, in particular, reflect the tra-

ditional social order of the communities and reinforce ties within and among families and households. The consumption, distribution, and exchange of marine resource products integrate the households and the community through a complex exchange network that reinforces cultural identity and social networks and provides important foodstuffs to households that are not able to hunt themselves.

Climate change, pollution, and governance are likely to be major factors in a vulnerability study of marine resource use communities in Greenland. Climate change and pollution could alter the availability, conditions, and health of animals such as seals and halibut, while changes in climate could affect the distribution and migration patterns of these animals, as well as ice and snow cover. Diminishing ice and snow cover could also have serious impacts on the mobility, hunting, and fishing activities of the residents of these communities. Climate alterations could further affect the ability of hunters and fishers to interpret and predict weather in planning safe and successful harvesting activities. Changes in politics, policies, and markets at local, national, and transnational levels could have negative or positive effects on the communities. Trade bans on marine mammal products, the increasing role that Home Rule and municipal governments play at the local level in towns and settlements, the growing importance of transnational policymaking forums, the financial support that individuals receive through transfer payments and subsidies, and consumption patterns of people near and far all have a bearing on the state of human–environment systems and their economies, social lives, and cultures. A vulnerability study would be useful in exploring how factors such as climate, pollution, and governance interact, their implications for human–environment systems, the resources Greenlanders might draw upon in reacting to social and environmental change, and the strategies that could be effective in guarding against negative consequences while capitalizing on opportunities.

17.4.2. A more advanced vulnerability case study

17.4.2.1. Reindeer nomadism in Finnmark, Norway

World reindeer herding

Reindeer herding is today the most extensive form of animal husbandry in the Eurasian Arctic and subarctic (also see Chapter 12). Some 2 million semi-domesticated reindeer (*Rangifer tarandus*) graze natural, contiguous mountain and tundra pastures covering an area of around 5 million km², which stretches from the North Sea to the Pacific Ocean (Fig. 17.5, Box 17.1). These reindeer provide the basis of the livelihood of herders belonging to some 28 different indigenous and other local peoples, from the Sámi of northern Fennoscandia (northern Norway, Sweden, and Finland) and the Kola Peninsula in northwest Russia, who herd approximately 500 000

Box 17.1. Biological adaptations by reindeer to life in the north (parts of this text have been published previously by Tyler and Blix, 1990)

Reindeer is one of only 13 out of 180 different species of ruminants that has been domesticated. The grazing areas of reindeer, however, cover almost 25% of land surface of the world (Turi, 1994). Reindeer inhabit a wide range of different biotopes. Like other species resident in the Arctic, reindeer are exposed to large seasonal variations in ambient light and temperature conditions and in the quality and availability of food.

The Arctic is a hostile place in winter, yet the cold, dark "polar wastes" sustain life. The environment is truly marginal and for this reason it might be thought that warm-blooded animals that spend the winter there must endure a truly marginal existence. However, most arctic animals usually neither freeze nor starve and it is therefore self-evident that they are well adapted to the several challenges of the natural environment in which they live.

Several species of monogastric mammals (i.e., those having a stomach with only one compartment) circumvent the problem of cold and the scarcity of food in winter by hibernating. Reindeer, however, are ruminants. Unlike monogastric species they have to remain active to feed continuously throughout winter. Moreover, they are truly homeothermic, requiring maintenance of a constant internal body temperature that is considerably above environmental temperature. For these, like other true homeotherms, the problem of survival becomes one of keeping warm. To do this they need both to reduce heat dissipation and to ensure an adequate supply of fuel, in the form of metabolites from food, for heat production. Therefore, adaptations for survival can be divided between those which help the animals to reduce their energy expenditure and those which help them to make best use of what little food they can find.

Reduction in energy losses

Reindeer and caribou have two principal defenses against cold. First, they are very well insulated by fur (e.g., Nilssen et al., 1984); second, they restrict loss of heat and water from the respiratory tract. In humans exposed to low ambient temperature but warmly dressed, the heat lost in exhaled air may account for more that 20% of metabolic heat production. In resting reindeer exposed to cold, by contrast, expired air is cooled and the animals are capable of conserving about 70% of the heat and 80% of the water added to the inspired air in the lungs (Folkow and Mercer, 1986).

Reduction in energy expenditure

Appetite and growth

Reindeer, like several other species of deer, show a pronounced seasonal cycle in appetite and growth which appears to follow an intrinsic rhythm entrained by photoperiod and associated with changes in levels of circulating hormones. In winter their appetite falls by as much as 70% of autumn values (Larsen et al., 1985; Mesteig et al., 2000; Tyler et al., 1999a). Growth slows or even stops (McEwan, 1968; Ryg and Jacobsen, 1982) and the animals begin to mobilize their fat reserves even when good quality food is freely available (e.g., Larsen et al., 1985). Intrinsic cycles of growth and fattening appear to be adaptations for survival in seasonal environments in which animals are confronted with long, predictable periods of potential under-nutrition. Slowed rate of growth and, to an even greater extent, actual loss of weight have the effect of reducing an animal's daily energy requirements (e.g., Tyler, 1987). This may be literally vitally important in winter when food is not only scarce and of poor quality but is also energetically expensive to acquire.

Activity

Besides minimizing heat loss in winter by means of increased insulation, reindeer and caribou can reduce energy expenditure by adopting appropriate behavior; in particular, by reducing the total daily locomotor activity. The nature of the surface over which animals travel is also very important. The relative net cost of locomotion in a caribou sinking to 60% of brisket height at each step is almost six times greater than the cost of walking on a hard surface (Fancy and White, 1985). The capacity of snow to support an animal depends on the hardness of the snow and the pressure (foot load) that the animal exerts on it. Thus, if snow hardness consistently exceeds foot loads, animals can walk on top of the snow or will sink to only a fraction of its total depth. The broad, spreading feet of reindeer and caribou, a well-known characteristic of this species, is clearly an adaptation to walking on snow, through minimizing the extent to which they break through the crust and sink in. Reindeer and caribou, with the exception of musk deer (*Moschus moschiferus*), have the lowest foot load measured in any ungulate

(Fancy and White, 1985). The potential significance of reducing locomotion as a means of saving energy is made clear from Fancy and White's (1985) calculation that the costs of locomotion for a 90 kg caribou breaking the trail at the head of the spring migration will represent an increment to its minimal metabolism of 82%. For the animals following the packed trail in its wake the incremental cost would be equivalent to about 33% of their minimal metabolism, a saving of more than half (Fancy and White, 1985).

Gathering and storing energy

Diet and digestion

Reindeer have an exceptional ability to cope with seasonal changes in the availability and quality of the different species of forage plants that they eat. This, together with the diversity of habitats in which the animals live, provides the basis for the capacity of reindeer to adapt toward climatic variability and change. Reindeer are highly adaptable intermediate mixed feeding types. They fall between true grazers that eat fibrous plants (25% of all species of ruminants) and concentrate selectors (40% of all species) that eat plants with low fiber content (Hofmann, 2000). By feeding selectively, they avoid highly fibrous plants and take, instead, the nutritious and easily digestible parts of a variety of different forage types including lichens, grasses, and some woody plants (Mathiesen et al., 1999, 2000; Storeheier et al., 2002a).

In some areas, the proportion of lichens in their diet increases in winter (Boertje, 1984; Mathiesen et al., 1999, 2000). Lichens are unusual as food for ruminants. They are rich in carbohydrate that is easily digestible in reindeer and are therefore also a good source of energy for the animals. However, they are deficient in nitrogen and minerals (Aagnes and Mathiesen, 1994; McEwan and Whitehead, 1970; Nieminen and Heiskari, 1989; Scotter, 1965; Storeheier et al., 2002a). Reindeer cannot, therefore, survive on lichens as their sole food supply. Ruminal fermentation of lichens has an important effect on ruminal absorption of energy rich volatile fatty acids in winter (Storeheier et al., 2003) and reindeer that eat lichens are better able to extract nitrogen from dietary vascular plants in winter (Storeheier et al., 2002b).

The consequences of increased temperatures over arctic ranges include an increase in the abundance of shrubs (Silapaswan et al., 2001; Strum et al., 2001) and a decrease in the abundance of lichens (Cornelissen et al., 2001). Reindeer herders report that the abundance and distribution of mountain birch (*Betula pubescens*) have increased and the abundance and distribution of mat-forming lichens have decreased in Finnmark over the last three to four decades. There are undoubtedly multiple causes underlying these changes. Thus, it is important to understand how reindeer can regulate their forage consumption to meet energy requirements under changing conditions. Though reindeer are able to survive without lichens in winter (Leader-Williams, 1988; Mathiesen et al., 1999; Sørmo et al., 1999) little is known about the level of production and the economy – and therefore, also, the vulnerability – of herding in lichen-free areas.

Fat

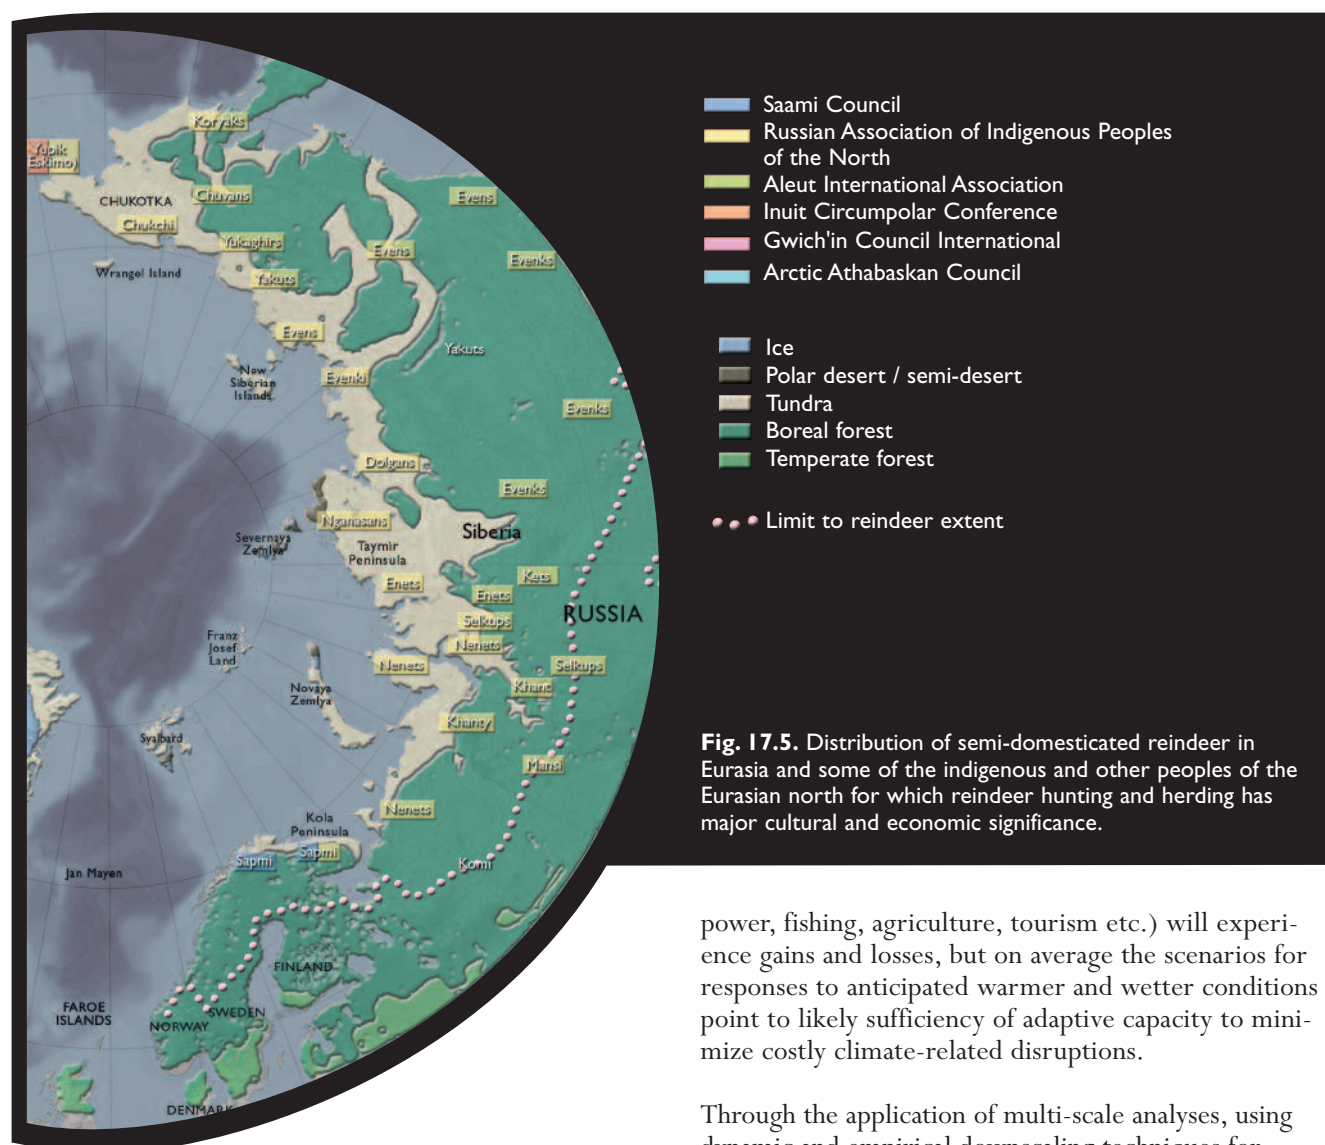
Many animals that live in highly seasonal environments store large amounts of energy as fat during summer and autumn in anticipation of food shortage during winter. In hibernating species, fat deposits may constitute up to 35% of the animals' total body weight. Ungulates, by contrast, usually store relatively little fat. The fat deposits of temperate and subarctic deer, for example, represent usually only between 4 and 10% of their total body weight in autumn (Tyler, 1987). Such low values cast doubt over the widely held view that fat is likely to be a major source of energy for deer and other ungulates in winter. Even using the most conservative models of energy expenditure it seems that the fat reserves of female Svalbard reindeer, the fattest of all reindeer, could contribute only between 10 and 25% of the animals' energy demands during winter (Mathiesen et al., 1984; Tyler, 1987). In practice, the contribution from fat is likely to be lower than these models predict because reindeer which survive winter do not normally use up all their fat (Tyler, 1987). Moreover, there is increasing evidence that the principal role of fat reserves in ungulates is to enhance reproductive success, rather than to provide a substitute for poor quality winter forage (although the very presence of fat will necessarily also provide insurance against death during periods of acute starvation). Substantial pre-rut fat reserves, for example, enable male deer to gather, defend, and serve their harems without being distracted by the need to feed and, in several species, males hardly eat at all for two or three weeks during the rut. It is more difficult to distinguish between alternative roles (reproduction and food supplement) for fat reserves in female ungulates because, in many species, these are pregnant throughout winter. Kay (1985) suggested that the principal role of fat reserves in females may be to supplement (but not to substitute for) their food intake during late pregnancy.


Fig. 17.5. Distribution of semi-domesticated reindeer in Eurasia and some of the indigenous and other peoples of the Eurasian north for which reindeer hunting and herding has major cultural and economic significance.

reindeer, to the Chukchi of the Chukotka Peninsula in the far east (Slezkine, 1994). The herding and hunting of reindeer has major cultural and economic significance for these people. Moreover, their herding practices, ancient in origin, represent models in the sustainable exploitation and management of northern terrestrial ecosystems that have developed and adapted *in situ* over hundreds of years to the climatic and administrative vagaries of these remote regions (Turi, 2002).

A Norwegian context

O'Brien, et al. (2004) asked whether Norway is vulnerable or resilient to future anthropogenic climate change (using projections from the ACACIA project, Parry, 2000). At a national level Norway can be considered relatively resilient and hence unlikely to be seriously affected by conditions forecast by climate scenarios over the next few decades. Its relative protection from hazards associated with sea-level rise, its weather-hardened architecture and infrastructure, its strong and equitable economy, its state of technological development, etc., all signal a good measure of resilience at the national scale. Certain economic sectors (oil and gas, hydro-

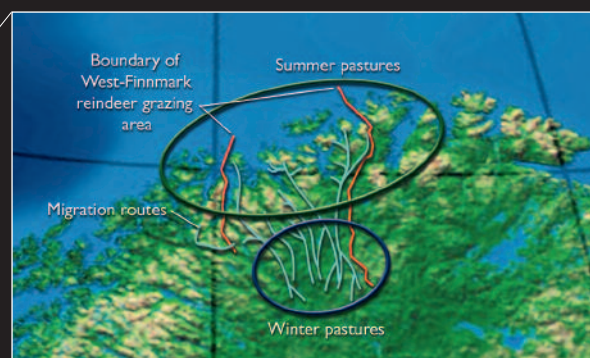
power, fishing, agriculture, tourism etc.) will experience gains and losses, but on average the scenarios for responses to anticipated warmer and wetter conditions point to likely sufficiency of adaptive capacity to minimize costly climate-related disruptions.

Through the application of multi-scale analyses, using dynamic and empirical downscaling techniques for regional and local climate scenarios, respectively, O'Brien, et al. (2004) were able to refine their assessments of vulnerability accordingly. Although climate extremes are not well captured in this analysis, it is clear that projections for differences in mean climate conditions vary greatly across Norway: northern, southwestern, and southeastern Norway fare quite differently. Only the first of these regions falls within the Arctic as defined in this chapter. Not surprisingly, it is this arctic portion of Norway that shows the greatest potential vulnerability to projected climate change; in large part due to the anticipated changes in natural ecosystems. The high dependence of human livelihoods on these resources, for economic and cultural reasons, contributes to a strong linkage between ecosystem changes and socio-economic consequences.

The primacy of fishing in many Norwegian coastal economies provides one example of such human–environment relationships. There is no historical analogue to allow confident predictions of fish stocks under a warmer coastal regime, and circulation changes in the North Atlantic may in fact be even more influential in determining the recruitment in key stock such as cod and herring. It is, however, likely that there will be changes in

Fig. 17.7. The present pattern of semi-domesticated reindeer migration in western Finnmark.

Fig. 17.6. World distribution of reindeer, showing Finnmark – the northernmost, largest, and least populated county in Norway (CAFF, 2001).

these marine ecosystems under projected climate regimes. Studies elsewhere reveal the difficulty that communities highly dependent on fishing have in adapting to alternative livelihoods when faced with permanently unfavorable changes in catch (Mariussen and Heen, 1998). Coastal areas in more temperate regions of North America and Europe contain many such examples.


Reindeer herding in northern Norway provides a similar example. Changes in temperature can affect vegetation and changes in the timing and form of precipitation can affect the animals' access to food. Either of these changes can influence the health and productivity of the herd, and hence the livelihoods and cultural practices of indigenous peoples who are highly dependent on this ecosystem.

O'Brien et al. (2004) also gave good examples of how the overall perspective on Norway's vulnerability could change with diminished importance of revenues from oil and gas over the next five decades (considered likely), and how climate impacts experienced in other nations can affect Norway via commerce, political relations, and movements of people. But an important underlying message is that for the foreseeable future the people most likely to be negatively affected by climate change are those whose lives are most intimately linked with terrestrial and marine ecosystems.

Finnmark Sámi reindeer herding

This analysis represents an interdisciplinary and intercultural approach to understanding the vulnerabilities

(*hearkivuohta*) of specific human–environment systems in the Arctic. As a work in progress it explores only some features of the human–environment system represented in reindeer nomadism. These features include climate and non-climate factors that impinge on, and may influence, the sensitivity and adaptive capacity of the system to environmental change. The perspective adopted here is that of members of local communities: the focus is on their interpretation of the concept of vulnerability analysis and on how it might usefully be applied to their situation. Thus, the information provided here is the result of a partnership between researchers and reindeer herders. The case study demonstrates how through active participation the reindeer herders modified and applied a general conceptual framework and interpreted research findings in a co-production of knowledge.

Finnmark is the northernmost, largest, and least populated county in Norway (Fig. 17.6). Within its 49 000 km² there live approximately 76 000 people, including a large proportion of Sámi. Populations of 114 000 reindeer and 2059 registered reindeer owners in Finnmark in 2000 represented 74 and 71% of semi-domesticated reindeer and Sámi reindeer owners in Norway, respectively (Reindriftsforvaltningen, 2002).

Reindeer in Finnmark are managed collectively in a nomadic manner rich in tradition. Herds of mixed age and sex, varying in size from 100 to 10 000 animals, are free-living and range in natural mountain pasture all year round. The herders typically make two migrations with their animals each year, moving between geographically separate summer and winter pastures. In spring (April and May), they and their animals generally move out to the mountainous coastal region where the reindeer are left on peninsulas or are swum or ferried across to islands where they feed throughout the summer, eating nutritious parts of bushes and shrubs, sedges, and grasses. In September the animals are gathered and taken inland to winter pastures in landscape typically consisting of open, upland plains of tundra and taiga birch scrub (Fig. 17.7, Paine, 1996; Tyler and Jonasson, 1993). The pattern of migration observed today is probably as much a legacy from earlier times, when Sámi moved to

the coast to fish in the summer and retired inland to hunt game in winter, as a reflection of the natural behavior of their reindeer. The autumn migration inland is clearly an adaptation to climatic conditions. Winters are mild and wet near the coast but colder and drier inland (Fig. 17.8). Consequently, the climate is more continental inland and cycles of thawing and re-freezing (which increase both the density and the hardness of the snow making it increasingly difficult for the animals to dig to the plants beneath) occur less frequently than at the coast. Grazing (snow) conditions are generally better inland as a result.

Reindeer herding in northern Norway has many advantages over herding throughout much of the rest of the Eurasian Arctic and subarctic. First, although the absolute number of animals is small (the population in Finnmark, for example, represents approximately 4% of semi-domesticated reindeer in Eurasia), the density of reindeer is very high. This reflects, in part, the relatively high productivity of this region, which, in turn, is a consequence of the warming effect of a branch of the North Atlantic Current. The overall density of approxi-

mately 2 reindeer per km^2 in Finnmark is roughly four times greater than the density of reindeer in Russia. Second, reindeer meat is regarded as a delicacy in Norway and in many years production fails to meet demand. This, in combination with the richness of the Sámis' traditional gastronomic culture, provides opportunities for development of the economic basis of their industry through small-scale family-based productions focusing on the concept of adding value. Third, northern Fennoscandia possesses well developed infrastructure and transport and an electronic communication network superior to that in any other region of the circumpolar Arctic at similar latitude. These three factors form the basis of a potentially robust and vibrant form of cerviculture. They also represent features of both the natural and the social environments that potentially influence the vulnerability of reindeer herding to the effects of climate variability and change.

17.4.2.2. Modifying the general vulnerability framework

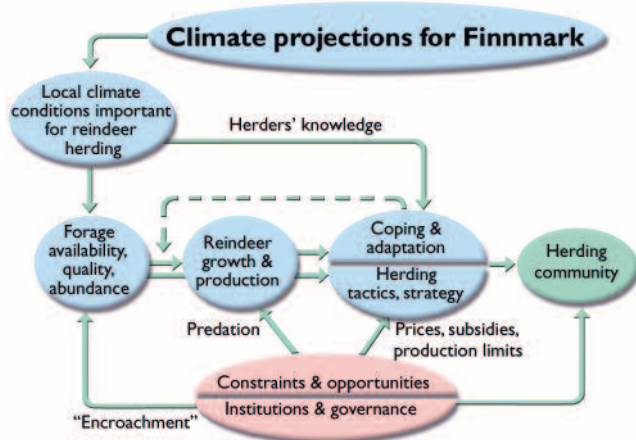
The first step in a vulnerability study is to evaluate the general methodological framework (Fig. 17.1) and modify it, where necessary, to suit the characteristics of the system of interest, in this case reindeer herding in Finnmark. A conceptual framework must be developed that focuses on the specific and, perhaps, even unique attributes of each particular case. Reindeer, reindeer herders, and the natural and social environments to which they belong represent a coupled human–environment system. Many of the components of this system, though only distantly related, are closely and functionally linked. Herders' livelihoods, for example, depend on the level of production of their herds. Production, in turn, depends on the size of herds and on the productivity of individual reindeer in them, which depend, again in turn, on the quantity and quality of forage available. The level of feeding the animals enjoy is determined in the short term by prevailing weather conditions including temperature in summer, which affects the growth and nutritional quality of forage plants, and by weather conditions in winter, in particular a combination of precipitation, temperature, and wind, which affect the quality of the snow pack and, hence, the availability of the forage beneath. In the medium and long term, however, feeding levels are also determined by a suite of non-climate factors all of which have a major influence on the level of production and, completing the circle, on the profitability of reindeer herding. These include the quality of pasture (in terms of the species composition and biomass of forage and the availability of other important natural resources), the area of pasture available, herders' rights of access to pasture, the level of competition between reindeer and other grazers, the level of predation to which herds are subjected, the monetary value of reindeer products and so on. Common to all these non-climate factors is that they are influenced by the decisions and policies of institutions far removed from Finnmark. Hence, it was clear at the outset that reindeer herding is a production system
Fig. 17.8. Monthly mean precipitation and temperature at Tromsø and at Karasjok in Finnmark (26° E, 69° N). Data are for 1961 to 1990 and the bars indicate 1 standard deviation (data supplied by the Norwegian Meteorological Institute).


Fig. 17.9. Conceptual framework for the Finnmark case study.

affected not just by climate variability, and potentially also by climate change, but also potentially very strongly by the socio-economic environment in which it exists.

A conceptual model relevant for reindeer herding in Finnmark was developed at a five-day meeting held in Tromsø in August 2002. The president of the Association of World Reindeer Herders drew together a team of natural scientists, social scientists, administrators, and reindeer herders. All the participants were encouraged to emphasize their own particular perspectives and, working together in this way, the group then revised the generalized conceptual framework to suit the conditions prevailing in Finnmark. The herders, for example, were largely responsible for selecting the principal components included in the final model and upon which the study was based. The customized framework (Fig. 17.9) describes the perceived relationships through which (1) climate change influences the growth and productivity of herds of reindeer, (2) herders cope with climate-induced changes in the supply of forage and in the level of production of their herds, and (3) herders' ability to cope with climate-induced changes is constrained by extrinsic anthropogenic factors collectively called "institutions and governance". (These include "predation", the level of which is influenced by legislation that protects populations of predators.) Each part was tempered with herders' understanding of the dynamics of herding, of their society, and of the natural and social environments in which they live. Superficially the final model (Fig. 17.9) bore little resemblance to the general framework (Fig. 17.1) from which it evolved, yet key elements, including human and environmental driving forces, human and societal conditions, impacts, responses, and adaptation, all remain.

17.4.2.3. Climate change and climate variability in Finnmark: projections and potential effects

Climate change is one of a suite of factors that influence the physical environment, the biota and, ultimately, the cultures of indigenous and other arctic communities. Large-scale climate changes in the Arctic will influence

local climate (e.g., Bamzai, 2003), which, in turn, can possibly affect foraging conditions for reindeer, the productivity of herds and, ultimately, herders' income and livelihood.

Projections for Fennoscandia

The climate of northern Fennoscandia is milder than at similar latitudes in Russia or North America owing to the warming effect of a northeastern branch of the North Atlantic Current, which flows north along the coast of Norway. The mean July temperature at the coastal town of Vadsø (70° 05' N) in northern Norway, for example, is approximately 11 °C, while that at Point Barrow (71° 30' N) in Alaska is approximately 4 °C. Likewise, the mean January temperature inland at Kautokeino (68° 58' N) is approximately -16 °C compared to approximately -35 °C at Old Crow (67° 34' N) in Canada (both located at similar elevations).

These differences notwithstanding, recent modeling indicates that during the next 20 to 30 years the mean annual temperature over northern Fennoscandia is likely to increase by as much as 0.3 to 0.5 °C per decade (Christensen et al., 2001; Hanssen-Bauer et al., 2000; Hellström et al., 2001; see also Chapter 4). The projected rise in temperature is greater in the north than in the south of the region, greater inland than at the coast, and greater in winter than in summer.

Confidence in these projections is based on the trend in mean annual temperature for the period 1970 to 2000, generated retrospectively by the same models, corresponding reasonably well with empirical observations. Figure 17.10, for example, illustrates the observed mean annual temperature measured at Karasjok, a representative inland grazing region used in winter, between 1900 and 2000 and a modeled projection for mean annual temperature for the period 1950 to 2050 (Hanssen-Bauer et al., 2000). The trend in the projection from 1970 to 2000 compares well with, and is not significantly different from, the observed temperature trends (Hanssen-Bauer et al., 2003). The models do not, however, capture the changes in variability which
Fig. 17.10. Low-pass filtered series of observed and projected mean annual temperature in Karasjok, eastern Finnmark. The projected temperature is downscaled from the ECHAM4/OPYC3 global climate model, run with the IS92a emissions scenario (Hanssen-Bauer et al., 2000).

have been observed. At this stage, therefore, it is not possible to project with any degree of confidence to what extent the variability in mean annual temperature in northern Fennoscandia is likely to change over the next 50 to 100 years.

Global projections for the next 70 years or so indicate increased precipitation at high latitudes. These projections seem robust (e.g., Räisänen, 2001) and are qualitatively consistent with the expected intensification of the hydrological cycle caused by increased temperatures. Regional models for Fennoscandia project an increase in annual precipitation of between 1 and 4% per decade (Fig. 17.11). The regional precipitation scenarios are, however, generally less consistent than the regional temperature scenarios and their ability to reproduce the trends observed in recent decades remains limited.

Increases in temperature and precipitation can potentially affect snow conditions in a variety of ways that can influence foraging conditions for reindeer. Increased temperature in autumn might lead to a later start of the period with snow cover and increased temperature combined with more frequent precipitation may increase the frequency of snow falling on unfrozen ground. Furthermore, increased precipitation in winter would be expected to contribute to increased snow depth at the winter pastures of reindeer. With increased temperatures, the melting period in spring might start earlier but the last date of melting might be significantly delayed where the initial snow cover is deeper. The physical structure of the snow pack could also be affected by the projected changes in temperature and precipitation. No local projections for snow conditions in Finnmark have, however, yet been made. Their development would require an integration of the projections for temperature and precipitation, both of which are currently available only at a coarse scale of resolution. To be meaningful, models would have to be downscaled and would need to incorporate data on the physical structure of the landscape, especially altitude which influences local temperature profiles and, hence, the transition of precipitation from rain to snow (e.g., Mysterud et al., 2000; see also Chapter 7).
Downscaling global projections

The spatial resolution of the projections for temperature and precipitation over northern Fennoscandia is very coarse and, consequently, of limited use for projecting local trends in any but the most general terms. Downscaled scenarios, designed to improve the spatial resolution of the projections, have been developed for temperature and precipitation at selected stations in Finnmark. Projections for Karasjok in eastern Finnmark are shown in Figs. 17.10 and 17.11. The downscaled temperature scenarios show some of the same characteristics as the regional scenarios for Fennoscandia, including greater warming in winter than in summer and inland compared to the coast. However, the inland–coast gradient was in most cases greater in the downscaled projections than in the global scenarios. Downscaled projections for precipitation did not match the global projections for Fennoscandia well. This result was not unexpected and reflects the fact that downscaling, unlike global modeling, is sensitive to the effects of local topography on patterns of precipitation.

Local climate conditions important for reindeer herding

To be manageable, the models developed by downscaling analysis were necessarily made very simple. The weather patterns over reindeer pastures, by contrast, are highly complex and display a large degree of regional, local, and temporal variation. Some of the temporal variation is apparent from data for particular parameters. The observed winter precipitation in Karasjok, for example, has varied during the last five decades from less than half the 1961–1990 average to almost twice this value (Fig. 17.12). Likewise, at Tromsø at the coast, the date on which the last snow disappeared (between 1960 and 2000) has varied by as much as 60 days from year to year. There is also considerable spatial variability: the mean annual precipitation for Finnmark (1961–1990), for example, ranges from 325 mm at Kautokeino (inland) to 914 mm at Loppa (coast). The situation is, however, more complicated than these simple comparisons indicate owing to the many ways in which weather

Fig. 17.11. Low-pass filtered series of observed and projected annual precipitation in Karasjok, eastern Finnmark. The projected precipitation is downscaled from the ECHAM4/OPYC3 global climate model, run with the IS92a emissions scenario (Hanssen-Bauer et al., 2000).
Fig. 17.12. Winter precipitation anomalies for Karasjok (eastern Finnmark) and Vardø (northeastern Norway), 1950 to 2001. The anomalies are given in percent relative to the 1961–1990 average.

can vary. Data collected over 35 years from two weather stations in central eastern Finnmark reveal, for example, that almost every year is a record year. Every year one parameter or another is colder, or warmer, or earlier, or deeper, and so on than ever before. There are, in effect, no "normal" years in Finnmark; instead, every year is exceptional. In herders' parlance: *Jahki ii leat jagi viellja* ("One year is not another's brother").

The challenge, therefore, is to extract data from global, regional, or local meteorological records in the form of selected parameters that, singly or in combination, represent useful proxies for those aspects of the weather in this complex system that significantly influence the growth and survival of reindeer and the work of the herders who look after them. Ecologists select proxies that are either as highly generalized or as highly specific as possible, including major atmospheric phenomena such as the North Atlantic Oscillation or monthly mean records of precipitation from a particular local weather station, respectively. The application of either highly

generalized or highly specific data can be useful and can yield robust results. The selection of proxies, however, is largely arbitrary and the results lack the sophistication that characterizes herders' understanding of the ways in which short-term variation in weather and longer term variation in climatic conditions affect their lives. Reindeer herders, like other people whose livelihood depends on close reading of the natural environment, have a deep understanding of the significance of the changing patterns of weather (Box 17.2). An important step in a vulnerability analysis of this kind, therefore, is to describe the effects of temporal and regional variation in weather on grazing conditions in terms of herders' experience and, hence, to identify climate phenomena and thresholds that are potentially important for reindeer production.

17.4.2.4. Ecological impacts

The ecological impact of large-scale climate variability and recent climate change on temperate species of

Box 17.2. The significance of snow

Reindeer herders, like other people whose livelihood depends on close reading of the natural environment, have a deep understanding of the significance of changing weather patterns. This knowledge is based on generations of experience accumulated and conserved in herding practice. Herders' understanding of snow (*muohta*) is one example.

In winter, each herding group grazes their animals in a defined area to which it has usufructory rights. In Finnmark, herds are typically tended continuously in winter, with herders taking watches that last seven to ten days. Their daily duties include maintaining the integrity of their herds – by preventing animals from straying and by keeping other reindeer away – and, most importantly, by finding fresh places for the animals to graze. "Good grazing" is a place where the snow is dry, friable, and not too deep to prevent the animals easily digging through it to reach the plants beneath. "Bad grazing" is a place where the snow is icy, hard, and heavy, or where a layer of ice lies over the vegetation on the ground beneath. "Exhausted grazing" is a place where reindeer have already dug and trampled the snow, consequently rendering it hard and effectively impenetrable.

Snow lies in the mountain pastures of northern Norway for up to 240 days per year and it is therefore not surprising that herders have learned to cope with varying snow conditions. The significance of snow for the lives of the people probably increased when they turned from hunting reindeer to herding them (Ruong, 1964). Winter grazing conditions must have become an important determinant of trade and, hence, an important topic of discussion. The distribution of snow and its physical characteristics such as its depth, hardness, density, structure, and variability all had to be expressed in a linguistic form. The Sámi recognize about 300 different qualities of snow and winter pasture – each defined by a separate word in their language (Eira, 1984, 1994; Jernsletten, 1997; Pruitt, 1979; Ryd, 2001).

A selection of Sámi words for snow

Čearga	Hard-packed drift snow "which one can't sink one's staff into"– impossible for reindeer to dig through.
Čiegar	Snow that has been dug up and trampled by reindeer, then frozen hard.
Fieski	Snow in an area where only a few reindeer have been, evidenced by few tracks.
Oppas	Thickly-packed snow through which reindeer can dig if the snow is of the *luotkku* (loose) or *seanas* type.
Sarti	A layer of frozen snow on the ground at the bottom of the snow pack that represents poor grazing conditions for reindeer.
Seanas	Dry, coarse-grained snow at the bottom of the snow pack. Easy for reindeer to dig through. Occurs in late winter and spring.
Skárta	A thin layer of frozen, hard snow on the ground that forms after rain. Also poor grazing conditions.

plants and animals is well documented (Ottersen et al., 2001; Post and Stenseth, 1999; Post et al., 2001; Stenseth et al., 2002; Walther et al., 2002). Among northern ungulates, variation in growth, body size, survival, fecundity, and population rates of increase correlate with large-scale atmospheric phenomena including the North Atlantic Oscillation (Forchhammer et al., 1998, 2001, 2002; Post and Stenseth, 1999) and Arctic Oscillation (Aanes et al., 2002). Putative causal mechanisms underlying these correlations involve the climatic modulation of grazing conditions for the animals. The effects may be either direct, through the influence of climate on the animals' thermal environment or the availability of their forage beneath the snow in winter (e.g., Forchhammer et al., 2001; Mysterud et al., 2000), or indirect, through modulation, by late lying snow, of the phenological development and nutritional quality of forage plants in summer (e.g., Mysterud et al., 2001). The consequences for the animals may, in turn, be either direct, involving the survival of the current year's young, or indirect, whereby climate-induced variation in early growth influences the survival and breeding performance of the animals in adulthood (e.g., Forchhammer et al., 2001).

Some well-established reindeer populations characteristically display high-frequency, persistent instability (e.g., Solberg et al., 2001; Tyler et al., 1999b) indicating that their dynamics, and the dynamics of the grazing systems of which they are a part, may be strongly influenced by variation in climate (Behnke, 2000; Caughley and Gunn, 1993). However, despite a substantial volume of research related to the effects of snow on foraging conditions in tundra and taiga pastures (Adamczewski et al., 1988; Collins and Smith, 1991; Johnson C. et al., 2001; Miller et al., 1982; Priutt, 1959; Skogland, 1978) and, more recently, research related to the effects of variation in summer weather on forage (e.g., Lenart et al., 2002; Pentha et al., 2001; Van der Wal et al., 2000), only little evidence of a strong and pervasive influence of large-scale climate variation on the rate of growth of populations (Aanes et al., 2000, 2002, 2003; Post and Stenseth, 1999; Solberg et al., 2001; Tyler et al., 1999b) or the performance of individual reindeer (Post and Stenseth, 1999; Weladji et al., 2002) has yet emerged.

17.4.2.5. Coping with climate variability and change

The potential impact of climate variation and change on the productivity of herds can be ameliorated by tactical and strategic changes in herding practice. Herders' responses (feedback) represent coping (*birgehallat*), indicated by the dotted line in Fig. 17.9. The conceptual framework proposes that responses may be triggered at two levels. Ultimately, the herders respond to climate-induced changes in the performance of their animals. They also respond directly to the kinds of weather conditions that are important for suc-

cessful herding. This proximal response is indicated by the line marked "Herders' knowledge" in Fig. 17.9. The model makes no assumption about the extent or effectiveness of herders' ability to cope or the magnitude of the influence of climate change on the system.

A major point emphasized in this study is that climate change is not a new phenomenon in eastern Finnmark, even over the timescale of human memory. Systematic records of meteorological data have been made at Karasjok, close to the winter pastures, since 1870. These data provide clear evidence of climate change during the last 100 years. The dominant features of the temperature and precipitation records displayed in Figs. 17.10 and 17.11 are not the overall trends but, rather, the substantial decadal variation. Hence, although temperature displayed no statistically significant trend during the course of the last century, it is readily apparent that between 1900 and 2000 inner Finnmark experienced two periods with generally increasing temperatures. Between 1900 and 1935 and again between 1980 and 2000 the mean annual temperature at Karasjok increased by about 0.5 ℃ per decade. The observed rate of increase closely matches the projections for warming over Fennoscandia over the next 20 to 30 years that lie in the range of 0.3 to 0.5 ℃ per decade (see Chapter 4). Similarly, the modest net increase in precipitation during the last century, which occurred at a rate of 1.6% per decade, belies the observation that there were, in fact, three separate and substantial periods of increasing precipitation in those years. Between 1945 and 1965, for example, the mean annual precipitation at Karasjok increased by 20%. The rate of increase during this event greatly exceeds the current projections for precipitation increase over Fennoscandia of 1 to 4% per decade (see Chapter 4). Projections for future temperature and precipitation fail to capture these rapid changes and, instead, reflect only the modest trends observed across the 20th century as a whole.

Sámi reindeer herders have therefore, in the course of the last century, been exposed to climate change events of a magnitude at least as great as – and in some cases much greater than – those currently projected for northern Fennoscandia over the next 20 to 30 years. It needs to be noted, however, that a reoccurrence in the future of the large variations in climate experienced historically is certainly not excluded in the projections of climate change. Moreover, what is likely to be unprecedented historically is the level of mean climate around which these fluctuations will occur. One potentially useful approach to predicting the likely impact of, and herders' responses to, climate change, therefore, is to explore how they were affected in the past and what responses they displayed then. This kind of exploration requires the codification and analysis of herders' responses to weather-related changes in foraging conditions and of their perception and assessment of the risks associated with different coping options.

Strategic responses

Diversity in the structure of herds

Aboriginal production systems in extreme, highly variable, and unpredictable climates are based on the sequential utilization of, often, a large number of ecological or climatic niches (Murra, 1975). The essence of such systems is flexibility and the distribution of risk through diversity. Reindeer herders maintain high levels of phenotypic diversity in their herds with respect, for example, to the age, sex, size, color, and temperament of their animals (Oskal, 2000). A *čappa eallu* ("beautiful" herd of reindeer) is, therefore, highly diverse and, in this respect, is the antithesis of a purebred herd of livestock of the kind developed by careful selection to suit the requirements of a modern, high yielding agricultural ruminant production system.

The traditional diversity in the structure of reindeer herds is an example of a coping strategy aimed at reducing the vulnerability of the herd to the consequences of unfavorable – and unpredictable – conditions. Thus, in traditional reindeer herding, even apparently "nonproductive" animals of either sex have particular roles which, when fulfilled, contribute significantly to the productivity of the herd as a whole. Traditionally, for example, reindeer herds in Finnmark typically consisted of as many as 40% adult males. Large numbers of large males were required for traction; they acted as focal points, helped keep the herd gathered, and reduced the general level of activity of the females: in modern jargon, the males contributed to energy conservation within the herd. Many were carefully castrated to this end (Linné, 1732). Their strength, moreover, enabled them to break crusted snow and to smash ice with their hooves, opening the snow pack to gain access to the plants beneath to the benefit of themselves and – incidentally – also for the females and calves in the herd. The modern agronomist, however, considers adult males unproductive and today few herds in Finnmark have more than 5% males. Males' role as draft animals and in gathering and steadying the herd has been largely superceded by snowmobiles – albeit at greatly increased economic cost. The reliance on snowmobiles, moreover, renders herding early in winter difficult in years when little or no snow arrives before the New Year. But old ways sometimes die out only slowly and there are ingenious solutions. When asked recently (in 2002) why he kept several heavy, barren females in his herd, Mattis Aslaksen Sara, a herder from Karasjok, replied "I have so few big males now – so who else will break the ice?" The decline in the diversity of the herd structure and, specifically, the increased proportion of females in today's herds is largely a result of government intervention. It reflects the influence of practices copied from sheep production systems that have been translated to reindeer herding by agronomists. The reduced heterogeneity of herds represents a reversal of the traditional approach; its consequences, in terms of the performance of the animals, remain largely unknown. The pattern of dispersion of female-dominated herds over the landscape is said to be different. The consequences of reduced heterogeneity in terms of changes in the vulnerability of the herding system to environmental change remain completely unknown.

Pastoral nomadism

The characteristic seasonal pattern of movement reflects herders' responses to the spatial and temporal heterogeneity and unpredictability of key resources, usually forage or water, whether these be for goats or cattle on a tropical savannah (Behnke et al., 1993) or for reindeer on northern taiga (Behnke, 2000). Nomadism is adaptive in the sense that, by moving his herd, the herder gains or averts what he anticipates will be the advantages or undesirable consequences of his doing so or not doing so, respectively.

Tactical responses

Movement

For Sámi nomads, one principal feature of the natural environment that influences the pattern of movement of herds into, within, and out of winter pastures is the condition of the snow pack. Snow determines the availability of forage (crusted snow is bad) and, in late winter, the mobility of herds (crusted snow is good). Skilled herders observe how the snow drifts, how it settles, and where conditions remain suitable for grazing and then make decisions about how and when to move after assessing the physical quality of the snow pack in relation to topography, vegetation, time of year, and condition of the animals. In the warm winters of the 1930s (see Fig. 17.10), for example, conditions were sometimes so difficult owing to heavy precipitation that herds spread out and moved to the coast earlier than normal in spring. Today, neighboring herding groups (*siida*) may even "trade" snow in the sense that one group may allow its neighbors to move their herd to an area of undisturbed snow (good grazing) on the former's land. In every case, success is contingent on the freedom to move.

Feeding

Reindeer husbandry in Norway is based on the sustainable exploitation of natural pasture. In winter, access to forage can be restricted by deep snow or ice and the animals have to cope with reduced food intake as a result. So extreme were snow conditions in the winter of 1917/18, with ensuing loss of animals, that Sámi herders in Norway employed Finnish settlers to dig snow to improve access to forage. Herders often provided small amounts of lichen both to reward animals they were in the process of taming and also as a supplement for draft animals or for hungry ones. Gathering lichens, however, is laborious and, instead, in addition to locally produced grass converted into hay or silage, several commercially available pelleted feeds have been developed (Aagnes et al., 1996; Bøe and Jacobsen, 1981; Jacobsen and

Skjenneberg, 1975; Mathiesen et al., 1984; Moen et al.,
1998; Sletten and Hove, 1990). The provision of small
amounts of supplementary feed can help to improve
survival in winter (especially for calves), to increase the
degree of tameness of the herd, and to improve the ani-
mal welfare image of reindeer herding in the eyes of the
public. Negative effects include increased frequency of
disease (Oksanen, 1999; Tryland et al., 2001) and
increased cost. The use of pellets and locally harvested
grass increased throughout Fennoscandia in the 1990s;
reflecting this, many petrol stations in the reindeer herd-
ing areas of northern Finland now stock sacks of feed
during winter. The use of pellets is less widespread in
Norway owing in part to its high cost: the grain products
in pelleted ruminant feeds are heavily taxed in Norway
and the cost of providing artificial feed for reindeer is
between four and six times higher than in Finland.
In Norway, therefore, use of feed is generally restricted
to periods of acute difficulty. This pattern might alter,
however, in future should snowfall increase substantially.

17.4.2.6. Constraints on coping

The strategic and tactical decisions herders make in
response to changes in pasture conditions represent
aspects of coping. The success of the kinds of responses
outlined in the previous section, however, depends to a
large extent on herders' freedom of action. This section
outlines five constraints or potential constraints on this
freedom of action. The first four concern government
policy (state, regional, and municipal) and present insti-
tutional arrangements that reduce the herders' ability to
respond creatively to changing conditions, including
climate variability and change. The fifth is pollution.

In Norway, Sámi reindeer herding takes place in a com-
plex institutional setting heavily influenced by various
forms of governance (see Fig. 17.1) that constrain
herders' options. Constraints include the loss of habitat,
predation (where the abundance of predators and,
hence, the rates of mortality due to predation, is influ-
enced by legislation protecting predators), and the
governmental regulation of herding (including the regu-
lation of rights of pasture, of the ownership of animals,
and of the size and structure of herds) and of market-
and price-controls. The effects of non-climate factors
like these on the development of reindeer herding
potentially dwarf the putative effects of climate change
described previously. Institutions and governance have
since the early 1980s demonstrably reduced the degree
of freedom and the flexibility of operation under which
reindeer herders traditionally acted. Their ability to cope
with vagaries of climate may be reduced as a result. For
these reasons, institutions and governance were included
as a major element in the conceptual model (Fig. 17.9).
The challenge remains to identify and quantify their
impact on reindeer herding and to identify and under-
stand the effects of this on herders' ability to cope with
and adapt to changing environmental conditions. Of
course, not all forms of governance and institutions are
negative for reindeer herding: central administration also

provides important protection and opportunities for the
industry and has supported both research and education.
Interestingly, a major development in government sup-
port for reindeer herding was precipitated by an
extreme climatic event. Severe icing over the pasture
during the winter of 1967/68 resulted in substantial
starvation and loss of reindeer in Finnmark. The govern-
ment responded in an unprecedented manner and pro-
vided compensation equivalent, in today's monetary
terms, to US$ 6.5 million. Out of this action arose a
debate among the Sámi regarding the division and distri-
bution of government funds within the reindeer indus-
try, which continues, in one form or another, to this day.
Loss of habitat, predation, the economic and socio-
political environment, and law, however, were factors
highlighted at the co-operative meeting in Tromsø (see
section 17.4.2.2): their legitimacy and relevance lie in
the fact that they are based on herders' subjective evalu-
ation of their own situation.

Loss of habitat

Reindeer herding is a highly extensive form of land use.
Roughly 40% (136 000 km^2) of Norway's mainland is
designated reindeer pasture and within this area Sámi
herders have – at least in principle – the right to graze
their animals on uncultivated ground irrespective of
land ownership. Herders' rights of usufruct, however,
afford them neither exclusive access to the land nor
protection from the interests of other land users.
Conflicts of interest are common. For herders the prin-
cipal issue is generally the securing of habitat in which
to graze their reindeer. Indeed, the progressive and
effectively irreversible loss of the uncultivated lands
which reindeer use as pasture is probably the single
greatest threat to reindeer husbandry in Norway today.
Preservation of pastureland is, likewise, perhaps the sin-
gle greatest priority for sustaining the resilience of rein-
deer herding confronted by changes in both the natural
and the socio-economic environment.

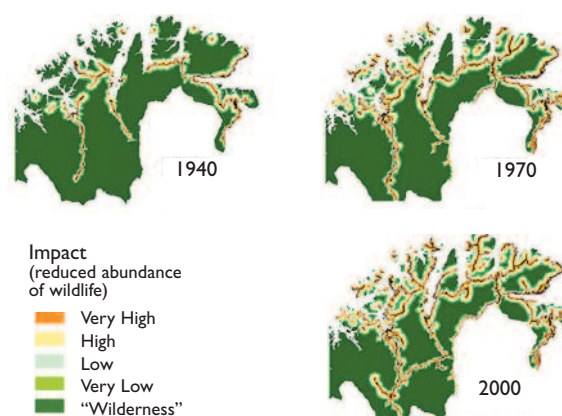
Habitat loss occurs in two main ways: (1) through phys-
ical destruction and (2) through the effective, though
non-destructive, removal of habitat or through a reduc-


Fig. 17.13. Encroachment of roads in Finnmark 1940 to 2000,
and the associated loss of reindeer pasture (UNEP, 2001).
Fig. 17.14. Projected development of infrastructure (including roads, houses, military training areas) in the Barents Euro-Arctic region 2000–2050. This scenario is based on the historical development of infrastructure, the distribution and density of the human population, the existing infrastructure, the known location of natural resources, distance from the coast, and vegetation type (GloBio, 2002).

tion in its value as a resource. Physical destruction of habitat is chiefly a result of the development of infrastructure, including the construction of artillery ranges, buildings, hydro-electricity facilities, pipelines, roads, etc. The effective removal of habitat may result from disturbance (for example, by hunters, fishers, and walkers), local pollution, increased grazing pressure by potentially competing species (e.g., sheep, Coleman, 2000) or through loss of rights of access either locally (Strøm Bull, 2001) or as a result of the closure of regional or international borders (Hætta et al., 1994). Taking Norway as a whole, piecemeal development of infrastructure has resulted in an estimated loss of 70% of previously undisturbed reindeer habitat during the last 100 years (Nellemann et al., 2003); in Finnmark, the figure is close to 35% for the last 60 years alone (Figs. 17.13 and 17.14).

Predation

Fennoscandia is home to the last remaining sizeable populations of large mammalian predators in Western Europe, including bear (*Ursus arctos*), lynx (*Lynx lynx*), wolf (*Canis lupus*), and wolverine (*Gulo gulo*). These species are all capable of killing medium-sized ungulates like reindeer (although bears probably rarely do this). Wolverine, a major predator for reindeer, were completely protected in 1981 though limited hunting is now permitted. In Norway, very large numbers of domesticated animals range freely in the mountain areas in summer, including approximately 2 million sheep and 140 000 reindeer (which remain at pasture both in summer and winter) and these, not surprisingly, are potential prey. Reindeer herders in Finnmark, the county with the highest losses, estimate that between 30 and 60% of their calves are taken as prey each year (Anon., 2003); in some herds losses exceed 90% (Mathis Oskal, reindeer herder, pers. comm., 2003). Losses on this scale dwarf all other causes of mortality including climate-related deaths (Reindriftsforvaltningen, 2002) and are therefore a major determinant of levels of production in herds.

Norway's mountain pastures are an important renewable natural resource: their management as pasture, however, is clearly complicated by the presence of predators and the resulting predation on grazing animals. Intervention designed to ensure the sustained usefulness of mountain pastures as a resource for grazing animals by reducing the density of predator populations to levels at which they no longer represent a threat to the livelihood of the sheep farmers and reindeer herders, must select from among several unsatisfactory alternatives. Consequently, any solution is likely to be an unsatisfactory compromise. Alternative strategies range from implementing a general reduction in the density of predator populations, to establishing "predator-free zones" where grazing can continue uninterrupted while leaving the predators elsewhere undisturbed. Any course adopted must be commensurate both with Norway's commitment to the conservation of viable populations of mammalian predators under the terms of the Convention on the Conservation of European Wildlife and Natural Habitats (the "Bern Convention") and other international agreements and, at least as far as reindeer are concerned, by the country's commitment to safeguarding the special interests of the Sámi people. This commitment is enshrined in the terms of the International Labour Organisation (ILO) Convention No. 169 on Indigenous and Tribal Peoples. Moreover, it seems apparent, as reindeer herders argue, that obligations with respect to the intentions of ILO Convention No. 169 may take precedence over those of the Bern Convention (Schei, no date; Uggerud, 2001) and they press for the establishment of predator-free zones accordingly.

In practice, the situation remains unclear. No predator-free zones have been created. The culling of predators takes place only on a limited scale and herders – who have the best local knowledge about the predators – are not normally permitted to take part. Compensation for loss of animals is generally paid only in cases where claims are substantiated with unequivocal evidence such as post-mortem examination of carcasses. Herders, however, normally determine losses by observing the absence of particular animals and are only rarely able to support their claims by producing a carcass; the gathering up, transport, and delivery of carcasses is generally impracticable. Consequently, their claims are mostly unsubstantiated and usually rejected: in 2001–2002 herders in Finnmark were compensated for only one in four reindeer claimed lost (Lund, 2002). Loss of reindeer through predation, possibly exacerbated by increased snow, therefore, remains a major constraint on herd production levels and the herders, furthermore, remain largely powerless to tackle the situation owing to legislation that runs counter to their immediate interests.

Economic and socio-political environment

Reindeer herding in Norway is the most regulated reindeer husbandry in the world today. In 2000, the annual cost of its administration was US$ 21 million, which was more than twice the amount paid to reindeer herders for their meat. (This refers to the raw product; the market value of the reindeer meat sold is substantially greater.) The current high level of regulation of herding dates from 1978 when Sámi reindeer husbandry was brought more closely under the management of the Royal Norwegian Ministry of Agriculture where economic planning remained the policy-makers paradigm. This development reflected an earnest desire to improve the economic basis of Sámi reindeer husbandry and, hence, help herders to achieve the stable income indispensable in modern society. Its consequence was that central government became one of the most potent forces shaping the development of reindeer herding. The reigning paradigm of government policy was that of a modern, agricultural food-production system and an immediate consequence of its implementation was an increase in the number of reindeer and reindeer herders (Anon., 1992). Today, policies established by the central administration influence virtually every aspect of reindeer husbandry, from the granting of licenses to own reindeer and the allocation of grazing rights, to the monitoring and regulation of the size-, age-, sex-, and weight-structure of herds, the setting of production quotas, the influencing of both the age and sex composition of animals selected for slaughter, the timing of slaughtering, and determining to which slaughterhouses herders must sell their animals.

Some aspects of government intervention have been necessary and valuable. Once the aboriginal system of pasturing rights (the *siida* system) ceased to be recognized by Norwegian law (Strøm Bull, 2001), an alternative governance structure was needed. Other government interventions, such as a centralized regulation of the price of reindeer meat, have resulted in stagnation in herders' economy. Political and market power was lifted from the hands of the herders in 1978 and consolidated in early 2000 when an alliance took place between *Norsk Kjøtt* (a meat farmers' co-operative which controls 75% of slaughtering in Norway) and two large, private, reindeer slaughterhouses neither of which are Sámi owned. Sámi ownership and control is minimal: in Norway only a small proportion of reindeer are slaughtered by Sámi-owned enterprises compared to a large proportion in both Sweden and Finland (Reinert and Reinert, in press). Import tariffs and pricing policies have been used to protect and promote the interests of agricultural meat production at the expense of reindeer herding interests. The market mechanism has been eliminated as a price setting mechanism for reindeer meat and, instead, its price is negotiated annually by the herders' organization (the Sámi Reindeer Herders Association of Norway) and the government. In reality, the negotiating power of the herders is minimal because *Norsk Kjøtt* is responsible both for the marketing

and the regulation of the reindeer meat market. For example, from 1976 to 1991 the net price paid to herders for their meat, corrected for inflation, fell by 45% largely in response to an increase in the level of production (Reinert and Reinert, in press). In the following decade the trend was reversed and the level of production was halved; yet, contrary to all normal practice, the real price paid to herders for their meat remained at the 1991 level. The absence of normal market mechanisms for price setting has been economically most disadvantageous for the herders. The fall in the price of reindeer meat over the last 25 years exemplifies the influence wielded over the economic development of reindeer husbandry by agricultural meat producers with vested interests. Lacking direct control over the slaughtering and marketing of reindeer meat, the Sámi of Norway became, *de facto*, an internal colony (Reinert and Reinert, in press). This recalls the term "Welfare Colonialism" coined by Paine (1977) to characterize culturally destructive colonialism in the Arctic.

Central administration, therefore, remains responsible for key aspects of the economic and socio-political environment in which herding exists and to which herders are obliged to adapt. The traditional fluidity and flexibility of practice that reindeer herding had developed to meet the vagaries of the natural environment of the north has been eroded. The exploration of the consequences of these developments for the adaptability, resilience, and vulnerability of Sámi reindeer herding under potential climate change remains, therefore, an important area of research.

Law

The elaborate legal structure upon which the regulation of reindeer husbandry is based is another aspect of the complex institutional setting in which Sámi reindeer herding is practiced in Norway. The law is comprehensive, complex and, occasionally, liberal to the point of ambiguity (Strøm Bull et al., 2001). It represents, therefore, a fourth non-climate factor that has a major influence on herding and which, by constraining herders' options, influences their ability to cope with changes in the natural environment.

Legislation governing reindeer husbandry is of considerable antiquity. A treaty agreed in 1751 between the respective joint kingdoms of Denmark/Norway and Sweden/Finland included the division along a common national border of hitherto undefined northern lands. This same border divides Norway and Finland today. The 18th century legislators realized that the creation of a border would potentially disrupt the lives of the nomads whose freedom of movement across the area had hitherto been unrestricted. An addendum was, therefore, included in the treaty confirming agreement between the two states that Sámi reindeer herders' customary utilization of the land should remain undisturbed notwithstanding the creation of a common border and the nomads' obligation to adopt one or other nationality.

This document, the Lapp Codicil, is the first formal legislation of reindeer husbandry. Crucially, it was built upon the principle of local self-government regarding the division of resources (Hætta et al., 1994).

The legislation of reindeer husbandry has evolved and increased in complexity since 1751. Successive statutes have been revised and new ones created to meet the challenges of changes in the economic and political climate, culminating in the Reindeer Husbandry Act of 1978 and its revision in 1996. Today's law includes provisions for the regulation of a wide range of issues. Section 2 alone includes rules for the designation of herding areas, the duration of grazing seasons within them, the size of herds, and the body mass of the animals in them. The level of detail of the legislation contrasts sharply with the lack of detail in the guidelines for its implementation. The Act is built on the premise that the organization of reindeer herding is best left in the hands of public administration. No groups have protected rights of usage. Instead, successive levels of the legislature – including the Ministry of Agriculture, the Reindeer Husbandry Board, Regional Boards, and Area Boards – determine, virtually unimpeded by legal barriers, the division of grazing districts, the allocation of herding franchises, and reindeer numbers. Regulation is achieved through rules, not statutes, as a consequence of which there remains considerable uncertainty among administrators and herders alike about the scope of the Act and a severe limitation of individual herder's opportunity to challenge administrative decisions.

The prevailing uncertainty is compounded by the fact that reindeer herding is regulated *de facto* by a Convention on Herding rather than through the provisions of the 1978 Act. The Convention is negotiated annually between the Government represented by the Ministry of Agriculture and the herders represented by the Sámi Reindeer Herders Association of Norway (NRL). The two parties are by no means equal. The Ministry is responsible both for drafting the regulations contained in each Convention, albeit in consultation with the NRL, and, ultimately, also for the interpretation and implementation of the final agreement. The regulations contained in the Convention are far more flexible than the Act but lack the legal checks and balances that the Act contains. The regulations agreed at each Convention, moreover, are frequently changed which only increases the level of uncertainty. Clearly, the complexities and ambiguities of the law contribute to the unpredictability of the administrative environment within which reindeer herding is practiced and, consequently, represent an important potential constraint on herders' ability to cope with changes in the natural environment.

Pollution

Pollution from sources outside the Arctic (AMAP, 2002) is another non-climate factor that can potentially influence the development of reindeer herding. Just as clean, local water is a fundamental human right, so also is the availability of uncontaminated food that can be gathered from traditional local sources. Imported agricultural food products are no substitute. Fortunately, chemical pollution is substantially less important for reindeer herding in Finnmark (generalizing from data for nearby regions in Russia) and, indeed, for all reindeer herding in Fennoscandia, than it is for marine resources (Bernhoft et al., 2002).

Most radioactive contamination on land in northern Fennocscandia is derived from fallout from atmospheric nuclear tests conducted up to 1980. Observed levels of contamination have not been considered hazardous for human health in Finnmark (Åhman, 1994; AMAP, 2004).

Radioactive contamination from the explosion at the Chernobyl nuclear power plant in 1986 is a major source of contamination in parts of southern Fennoscandia. This is a serious problem locally but is not directly a problem for reindeer herding as a whole because the majority of reindeer and reindeer herders live in the north of the region (Åhman, 1994). The radioactive pollution from Chernobyl has, however, been an indirect problem for the entire reindeer herding industry owing to negative focus in mass media, which failed to distinguish between those regions that received some fallout and those that were not affected at all. Misinformation of this kind can potentially turn consumers away and can encourage international food producers to step in and provide "clean", although non-traditional, substitute foods. The influence of effects of this kind on the vulnerability of small arctic enterprises like Sámi reindeer herding remains an important area of study.

Heavy metals accumulate in lichens (AMAP, 2002). Concentrations of heavy metals in reindeer meat, however, are no higher than in the meat of pigs, cattle, and poultry (Bernhoft et al., 2002). No data are available on concentrations of heavy metals in reindeer in Finnmark. Data on trends in heavy metals are available only for reindeer from Sweden where samples have been collected annually in three reindeer districts since the early 1980s (Swedish Museum of Natural History Contaminant Research Group, 2000). These data indicate that there have been no significant changes in the concentration of Pb, Cd, or Hg in reindeer meat for the period 1983 to 1998. In liver, the concentration of Pb decreased by 6.8% per year over this period, while the concentration of Cd showed a slight increase. Concentrations of Pb and Cd are very low (0.06 µmol/L) in blood among women in arctic Norway (Odland et al., 1999).

Cadmium is a potential problem owing to its tendency to accumulate in reindeer kidneys: people who consume these organs are exposed to this metal. AMAP (2002) reported that concentrations of Cd in reindeer kidneys in arctic Norway and Sweden are approximately three times higher than those in southern Norway and Sweden. Bernhoft et al. (2002) reported very low levels of Cd in the kidneys of reindeer from Kola in northwest Russia.

No data are available on concentrations of POPs in reindeer in Finnmark. In general, concentrations of POPs are lower in terrestrial mammals than in marine mammals (AMAP, 2002). Concentrations have been measured on an annual basis since 1983 in reindeer at Abisko, Sweden (AMAP, 1998). Current levels are not thought to represent a significant threat for reindeer (AMAP, 2002). Levels of two POPs in other species in the Swedish Arctic are declining, e.g., ΣDDT and ΣPCBs in otters in northern Sweden (Roos et al., 2001), and this trend is expected to continue.

17.4.2.7. Insights from the reindeer nomadism vulnerability case study

The reindeer nomadism vulnerability case study demonstrated the versatility of the general conceptual framework for vulnerability studies proposed in section 17.2. The development of a framework that was tailored specifically for reindeer herding in Finnmark also showed the diversity of the kinds of information that need to be included in an assessment of the vulnerability of a human–environment system in the Arctic. It illustrated the usefulness of reducing potential complexity to manageable proportions by developing a conceptual model containing just a few selected elements. It also showed the importance of collaborating with reindeer herders in a co-production of knowledge.

The validity and legitimacy of reducing an immensely complex system to something simple and, therefore, amenable to a vulnerability assessment depended wholly on the participation of herders themselves. Outsiders should not decide what factors, or suites of factors, influence reindeer herding: nobody, except for herders themselves, can legitimately make the required selection. The conceptual model, developed as a result of the interdisciplinary and intercultural effort, necessitated the integration of empirical data and herders' knowledge. The integration of different ways of knowing, called the "co-production of knowledge" (e.g., Kofinas and the communities of Aklavik, 2002), is not widely exploited in ecological research probably because aboriginal knowledge often does not lend itself to reductionist analysis and hypothesis testing. However, herders' knowledge of the impact of something as specific as climate variation on their way of life is based on an understanding resulting from generations of experience accumulated and conserved in herding practice and herders' specialized vocabulary. Consequently, in some instances herders can contribute knowledge gathered over a time span longer than the periods over which climate change has been documented by other means. The success of the approach outlined here was evident from the logical design and usefulness of the resulting conceptual model.

The joint effort in developing a conceptual model appropriate for a study of the vulnerability of reindeer herding in Finnmark to climate change quickly revealed that herding is affected by much more than just change in climate. Moreover, it is extremely likely that the effects on

reindeer herding of the non-climate factors introduced into the model potentially dwarf the putative effects of climate change on the system. Hence, the potential consequences of the projected increase in the average annual temperature at Karasjok over the next 20 to 30 years (Fig. 17.10) cannot meaningfully be considered independent of concurrent changes in the socio-economic environment for which, in some cases, clear predictions are already available (e.g., Figs. 17.13, 17.14).

Clearly, reindeer herding has been very resilient. The continued existence of nomadic reindeer herding by Sámi and other northern peoples in Eurasia today is evidence that these have, through the centuries, coped with and adapted to the vagaries and transitions of the socio-economic environment of the north. On one hand, it has not been overlooked that, if the marginalization of reindeer nomadism continues and if constraints on the freedom of action of the herders increase, new climatic conditions might threaten the resilience and increase the vulnerability of herding societies in ways that are without precedent. On the other hand, action provokes reaction: changes in climate and in the socio-economic environment might also create new opportunities for sustainable development in reindeer peoples' societies. Herders can be expected to grasp new opportunities, wherever they arise, and to take the initiative in improving the economy of their industry thereby reducing the vulnerability of their society.

17.5. Insights gained and implications for future vulnerability assessments

Arctic human–environment systems are subject to high rates of change in climate and/or other environmental and societal factors. Some changes emanate from outside the Arctic, while other changes arise from within the region. The vulnerability of human–environment systems in the face of such changes can vary widely with differences in the character and relative importance of environmental and societal changes across local settings. Vulnerability analysis offers an approach for exploring implications of environmental and social changes in a way that recognizes the interconnectedness of human and environment systems and the exposure, sensitivity, and adaptive capacity of these systems as they experience stresses or anticipate potential stresses arising from and interacting across local, regional, and global scales.

The Sachs Harbour and Greenland examples, plus the more developed case study on reindeer herding in Finnmark (section 17.4.2), reveal the importance of characterizing the place-based aspects of coupled human–environment systems, analyzing multiple and interacting stresses across multiple scales, accounting for adaptive capacity in assessing vulnerability, and incorporating varied forms of knowledge, analytical tools, and methodologies in vulnerability analysis. These case studies demonstrate that in their decision-making *arctic residents integrate their experiences and expectations of change in environmental and societal factors in addition to changes in climate and varia-*

tion in climate. They also illustrate that *vulnerability analysis can be applied in situations where the social and environmental changes important for a particular human–environment system operate at different scales.*

Given the close linkages between arctic peoples and the natural settings in which they live and on which they depend, a meaningful and useful analysis of arctic vulnerabilities requires the definition, characterization, and analysis of coupled human–environment systems. The human–environment systems at the heart of the case studies presented in this chapter are centered around human livelihoods (e.g., marine resource use). Seen from a human perspective, livelihoods are arguably the most salient aspect of a coupled human–environment system because the practices they entail involve close, fairly well-circumscribed, and critical interactions between social and natural systems in a particular locale, yet with discernible linkages to dynamics operating not only within, but also across local, regional, and global levels. Livelihoods are also the focal point of social organization, culture, and identity. The focus on reindeer herding in Finnmark, for example, enables the identification of specific climate-related changes (e.g., regarding snow pack and forage) and regulations (e.g., regarding land rights and predators) that affect this system. The identification of stresses, vulnerabilities, and response strategies for a more broadly defined system (e.g., for all indigenous peoples in Fennoscandia) would be more difficult and arguably less useful. The complex dynamics important for understanding vulnerability are apparent in all case studies. In Greenland and Sachs Harbour the size, health, and harvest of fish and marine mammals depend on climate, pollution, market factors, regulations, and technology. In Finnmark, climate changes and regulations have profound effects on reindeer, reindeer habitats, and herder practices and livelihoods. In Greenland with its market ties to distant localities via fish and fur products *it is evident that coupled human–environment systems in the Arctic are influenced by socio-political, socio-economic, and cultural factors originating outside as well as inside the region. Arctic residents accommodate this range of influences in their coping decisions.*

As these studies also show, primary stresses like climate change can have cascading and interacting impacts on many different aspects of the arctic physical and biological environment. Some factors, for example local climate shifts, can impact on many different components of the arctic system with differing magnitudes, timing, effects, and interactions. Thus, an increase in air and water temperature will probably affect the distribution of coastal winter sea ice and alter the access of local people to fishing and hunting areas; it may affect local oceanography and alter the habitats of marine mammals and their prey; it may increase the abundance of forage that reindeer eat; it may accelerate physical processes of pollutant transport and reactivity; and it may affect the health and well-being of arctic residents through decreased access to traditional foods and

increased incidence of disease, etc. Each of these effects can interact with others leading to more complex, higher-order effects. For example, the seasonal distribution and migratory routes of marine mammals may shift, forcing the hunters and their families either to follow the animals and relocate or to adopt new economies and lifestyles.

The case studies also illustrate *the importance of examining multiple, interacting stresses, operating within and across local, regional, and global scales, as well as the adaptive capacity of systems weathering these stresses.* Stresses (as well as potential opportunities) facing marine resource systems arise from interactions among, for example, climate, global markets, environmental and animal welfare campaigns, and changes in governance. Stresses (as well as potential opportunities) facing reindeer herding systems arise from interactions among changes in, for example, climate, forage, technology, and regulation. These factors do not, by definition, always lead to negative consequences. Changes in governance might be just as likely to reduce vulnerability as they are to contribute to vulnerability. A holistic understanding of vulnerability requires analysis of these many factors and their interactions, along with an understanding of how the coupled human–environment system in question might cope with or adapt to the changes brought about by these factors. *Coping and adaptation can diminish the vulnerability of certain components of the system and thereby offset adverse impacts. Vulnerability analyses reveal where actions can best be taken to enhance adaptive capacity, for example, via changes in public policy and new strategies in resource management, and anticipatory measures to prepare for adverse circumstances and mitigate their effects.* Arctic human and environment systems have a long history of coping with and adapting to social and natural changes. The resilience exhibited by arctic peoples provides insight into how these coupled human–environment systems might adapt in the future. Mobility, flexibility in livelihood (e.g., hunting, fishing, herding) practices, and a capacity for innovation all contribute to adaptive capacity, including a capacity to plan and prepare for contingencies. For example, the varied strategies that reindeer herders have developed for dealing with environmental and social changes are also strategies through which herders anticipate and prepare for future events. Nomadism itself is a way of anticipating future opportunities or adverse conditions. Because they are mobile, Sámi reindeer herders can respond quickly to unfavorable weather and/or snow conditions in one location by moving to another. "Trading" in snow is another practice that helps herders to successfully handle contingencies. An accounting of past and present adaptive measures is an important component of vulnerability assessment.

Vulnerability assessment also requires varied forms of knowledge and the development of new analytical tools and methodologies. Understanding the stresses facing place-based coupled human–environment systems and the adaptive measures they might take in response to

these stresses necessitates novel modes of inquiry. *Involving indigenous peoples and other arctic residents in the research process is extremely important in developing such understandings.* Methods to integrate indigenous knowledge and scientific knowledge such as biology, climate science, political science, and anthropology are similarly important. Climate downscaling, pollutant modeling, scenario development for societal trends, environmental monitoring, interviews, focus groups, workshops, and ethnography comprise additional approaches that could be integral to vulnerability analysis.

The following sections contain general conclusions pertaining to the assessment of trends in climate, pollution, and human and societal conditions, and some comments on next steps.

17.5.1. Climate

The results of downscaling analyses reported for Finnmark provide preliminary insights into how temperature and precipitation may change in this region. The projections presented in the Finnmark case study were calculated using a single domain (20º W–40º E and 50º N–70º N for Karasjok, Norway). A more comprehensive downscaling program would provide projections using multiple downscaling domains. The models presented here also use a single predictor variable: large-scale temperature for projecting local temperature, and large-scale precipitation for projecting local precipitation. It remains to be seen how sensitive the results are to the selection of downscaling domain or predictor variables. Also important to include would be downscaling results for a number of additional variables such as snow and ice cover, permafrost conditions, and extreme events, as well as sensitivity analyses to examine the robustness of the various projections. A more comprehensive program would also involve residents more directly in research design, analysis, and dissemination.

Effective downscaling must engage local people. Snow quality, for example, is an extremely important factor for reindeer herding and reindeer herders have many words to describe snow quality. In contrast, climate downscaling provides information about a relatively limited number of variables. It is therefore not obvious how typical climate forecasting products and terminology might be made relevant for reindeer herders. Thus, in principle, analysts conducting downscaling for a vulnerability study should first assimilate the views and information needs of local people for the products of these analyses. In practice this will require creative ways for presenting results to non-climate specialists in order to address their needs and concerns and make most advantage of their local knowledge. As with any climate analysis, the models used in this study produce an enormous quantity of information – all of which is important for the analysis but most of which may not be useful for decision-makers. The risk of information overload is high. For example, at a minimum, for each downscaled

climate variable, month, and general circulation model analyzed, vulnerability researchers should examine estimates of trend, variability, historical goodness-of-fit, and spatial distribution. Thus, climate analysts need to be willing to tailor their model products to the specific needs of local decision-makers.

17.5.2. Pollution

Information on POPs and heavy metals in the Arctic is widely available for the past two decades. Data on environmental concentrations for a number of chemicals exist for both western Greenland and Fennoscandia. These data, however, tend to be temporally and spatially dispersed. Data on local, long-term trends in environmental levels of POPs and heavy metals are much less abundant for both loci. There are, however, reliable time trends for certain species (e.g., reindeer and arctic char) in Fennoscandia. Data from the early 1980s to 2000 indicate generally declining environmental levels of POPs in both Disko Bay on the west coast of Greenland and in Fennoscandia. Trends in environmental heavy metal levels in western Greenland and Fennoscandia are less clear than for POPs. Some heavy metal levels have increased, while others show no change, or even a decrease.

Long-term local human trend data are even less available for western Greenland and Fennoscandia than environmental trend data. Available data suggest that observed human health problems relating to POPs and heavy metals are greater in western Greenland than in Fennoscandia. At the regional level, the greatest heavy metal threat to human health is due to Hg. Exposure to Hg in Greenland is at levels where subtle health effects can occur on fetal and neonatal development (AMAP, 2003). As in Fennoscandia, environmental heavy metal levels in the Disko Bay region show diverse trends. Daily human intake of Cd and Hg in the Disko Bay region is comparatively high.

Levels of POPs in both regions can be expected to decline toward 2020 due to increasing international regulation, although other POPs such as brominated flame retardants could become a growing problem (AMAP, 2002). Trends in environmental heavy metal levels to 2020 in both regions are more difficult to project than for POPs.

Future place-based pollutant research for vulnerability analysis would ideally consist of exposure and trend monitoring, human health and epidemiological analyses, and collection of other relevant data such as information about dietary intake, smoking, and other influences on pollutant burden. All these types of study are feasible and have been done at various sites; however, a vulnerability study necessitates that this information be available for a specific location. There is also a need to better understand local means of adaptation to problems with pollution, both in terms of what has been done and what could be done.

17.5.3. Trends in human and societal conditions

Several general trends (i.e., those concerning governance; population and migration; consumption; economy, markets and trade; and connectivity) are apparent in human and societal conditions throughout much of the Arctic. In recent decades, governing authority in Greenland and places within Canada and Alaska has rested increasingly with indigenous peoples. At the same time, regulations (particularly those pertaining to natural resource use) emanating from local, national, and international bodies are playing important roles in the lives of arctic peoples and the ways in which they are permitted to use land and to harvest fish and marine and terrestrial mammals. In addition, pan-arctic cooperation is increasing and transnational networks of indigenous peoples are growing. More people live in arctic urban areas than was the case thirty years ago, less traditional food is being consumed, a larger number and greater variety of imported technologies are employed, and people are more "wired" via the Internet, television, telephones, and satellites. Mixed economies have become more prevalent throughout the Arctic and the connections linking arctic economies with global markets are becoming stronger.

But while human and societal trends identified in this project are noteworthy for the Arctic as a whole, they by no means represent a complete inventory of such trends. Nor are they necessarily the most important trends for understanding the vulnerability of the case study sites. A more comprehensive and complete analysis of human and societal trends within the context of a fully-fledged vulnerability analysis would require the broad and systematic engagement of people living in the case study locations, and the use of tools such as surveys, participant observation, workshops, interviews, focus groups, and ethnography to ascertain what human and societal conditions are most relevant to a particular coupled human–environment system, how these conditions have changed over recent decades, and how they are expected to change in the future. The development of several alternative future societal scenarios would be useful in carrying out the difficult task of projecting future human and societal conditions and assessing their implications for coupled human–environment system vulnerabilities. The production and comparison of multiple scenarios could facilitate sensitivity analysis.

Oran Young (1998b) defined sustainable development as "…an analytic framework intended to provide structure and coherence to thinking about human/environment relations". Young calls for a sustainable development discourse that will facilitate efforts to identify and address arctic concerns. He adds that "To be useful in an arctic context, sustainable development must take into account the distinctive ecological, social, and cultural features of the region and offer an integrated approach to the endogenous and exogenous threats to sustainability peculiar to the circumpolar world". According to this

view, vulnerability (and resilience) analysis as outlined in this chapter, can serve as a vehicle for conceptualizing and implementing sustainable development. Vulnerability analysis offers a holistic vision of human–environment systems and their dynamics at local to global scales. It recognizes that environmental changes are interactive, that ecology, culture, economics, history, and politics are interconnected, and that decisions about what to sustain and how must be made in particular social and ecological contexts. However, vulnerability analysis is more than a research strategy. It has the potential to provide processes in which people with varied backgrounds and interests can engage in dialogue, produce knowledge, and articulate values. Such processes can ultimately inform the ways in which communities and governments balance aspirations for human and societal development with those of environmental and social sustainability.

Contents

18.1. Introduction

This chapter provides a brief summary of the main conclusions of the seventeen preceding chapters of the Arctic Climate Impact Assessment (ACIA). The chapter has three main parts. The first part contains the conclusions of the assessment discussed chapter by chapter. Observed climate and ultraviolet (UV) radiation trends (Chapters 2 and 5) are summarized, using both scientific and indigenous (Chapter 3) observations, and information from the latest assessments by the Arctic Monitoring and Assessment Programme (AMAP, 1998) and the Intergovernmental Panel on Climate Change (IPCC, 2001). Projections of climate change over the 21st century, based on emissions scenarios and computer model simulations (Chapter 4) are described, as are the observed and projected changes in stratospheric ozone and UV radiation levels (Chapter 5). Next, the chapter summarizes arctic-wide consequences of climate change, by examining impacts on the environment (Chapters 6, 7, 8, and 9), on people's lives (Chapters 10, 11, 12, 15, and 17), and on economic sectors of importance in the Arctic (Chapters 13, 14, and 16). These impacts cut across the entire Arctic and are generally not dependent on resolving regional details. For example, the timing, intensity, and magnitude of the melting of snow and ice in a warmer climate will have widespread implications for the entire Arctic and the global environment, even if these changes vary regionally.

Projected major large-scale environmental changes in the Arctic are illustrated in Fig. 18.1, which shows the existing and projected boundaries for summer sea-ice extent, permafrost, and the treeline. The likely changes associated with these shifts are many and dramatic, as described in the preceding chapters of this assessment. For example, the map shows that the treeline is projected to reach the Arctic Ocean in most of Asia and western North America by the end of the century. This is likely to lead to a near total loss of tundra vegetation in these areas, with important consequences for many types of wildlife. The consequences of the permafrost thawing and sea-ice reductions shown in Fig. 18.1 are equally dramatic.

The second part of the chapter is a synthesis of impacts on a local and regional basis, providing details on four different regions of the Arctic. A regional emphasis is necessary because the Arctic covers a large area and so experiences significant regional variations in the changes in climate that will lead to different impacts and responses. Different regions also have different social, economic, and political systems, which will each be influenced differently, causing vulnerability and impacts to differ to a large extent on the basis of geopolitical and cultural boundaries. The four regions for which results are presented are:

- Region 1: East Greenland, the North Atlantic, northern Scandinavia, and northwestern Russia;
- Region 2: Siberia;
- Region 3: Chukotka, the Bering Sea, Alaska, and the western Canadian Arctic; and
- Region 4: the central and eastern Canadian Arctic, the Labrador Sea, Davis Strait, and West Greenland.

The rationale for selecting these four broad regions includes climatic, social, and other factors, and is discussed in section 18.3.

The final part of the chapter addresses cross-cutting issues that are important in the Arctic. These are discussed in several chapters of the assessment, although usually in the context of the main topic of the chapter, and include the carbon cycle, biodiversity, and extreme and abrupt climate change.

Changes in climate and UV radiation in the Arctic will not only have far-reaching consequences for the arctic environment and its peoples, but will also affect the rest of the world, including the global climate. The connections include arctic sources of change affecting the globe, e.g., feedback processes affecting the global climate, sea-level rise resulting from melting of arctic glaciers and ice sheets, and arctic-triggered changes in the global thermohaline circulation of the ocean.

The Arctic is also important to the global economy. There are large oil and gas and mineral reserves in many parts of the Arctic, and arctic fisheries are among the most productive in the world, providing food for millions (see section 18.2.2.3). Climate change is likely to benefit north–south connections, including shipping, the global economy, and migratory birds, fish, and mammals that are important conservation species in the south. The Arctic plays a unique role in the global context and climate change in the Arctic has consequences that extend well beyond the Arctic.

18.2. A summary of ACIA conclusions

18.2.1. Changes in climate and UV radiation

18.2.1.1. Observed climate change

The climate of the Arctic has undergone rapid and dramatic shifts in the past and there is no reason that it could not experience similar changes in the future. Past changes show climatic cycles that have occurred regularly on time scales from decades to centuries and longer and are most likely to have been caused by oceanic and atmospheric variability and variations in solar intensity. Examples of long-term cooler and warmer climates were the Little Ice Age and the Medieval Warm Period, respectively, while short-term decadal cycles like the North Atlantic Oscillation and Pacific Decadal Oscillation, among others, have also been found to affect the arctic climate. Since the industrial revolution in the 19th century, anthropogenic greenhouse gas (GHG) emissions have added another major climate driver. In the 1940s, the Arctic experienced a warm period, like the rest of the planet, although it did
Fig. 18.1. Present and projected boundaries of summer sea-ice extent, permafrost, and the treeline. The changes are projected to occur over different time periods. Changes in summer sea-ice extent will occur by the end of the century, as projected by the five-model composite used by the ACIA (section 6.3, Figs. 6.3b and 6.9c). The projected changes in the treeline by the end of the century are from a vegetation model driven by output from the Hadley Centre model (section 7.1.1, Fig. 7.2 and section 7.5.3.2, Fig. 7.32). The change in the permafrost boundary assumes that the present areas of discontinuous permafrost (section 6.6.1, Fig. 6.21, although published sources differ) will be free of any permafrost in the future; this is likely to occur beyond the 21st century but it is not certain how long it will take.

not reach the level of the warming experienced in the 1990s. The IPCC stated that most of the global warming observed over the last 50 years is attributable to human activities (IPCC, 2001), and there is new and strong evidence that in the Arctic much of the observed warming over this period is also due to human activities.

Chapter 2 discusses the arctic climate system and observed changes in arctic climate over recent decades. Many types of observations indicate that the climate of the Arctic is changing. For example, air temperatures are generally warmer, the extent and duration of snow and sea ice are diminishing, and permafrost is thawing. However, there are also some regions where cooling has

occurred, and some areas where precipitation has increased. Reconstruction of the history of arctic climate over thousands to millions of years indicates that there have been very large changes in the past. Based on these indications that the arctic climate is sensitive to changes in natural forcing factors, it is very likely that human-induced factors, for example the rise in GHG concentrations and consequent enhancement of the global green-house effect, will lead to very large changes in climate, indeed, changes that will be much greater in the Arctic than at middle and lower latitudes.

The observed temperature changes in the Arctic over the five-decade period from 1954 to 2003 are shown in

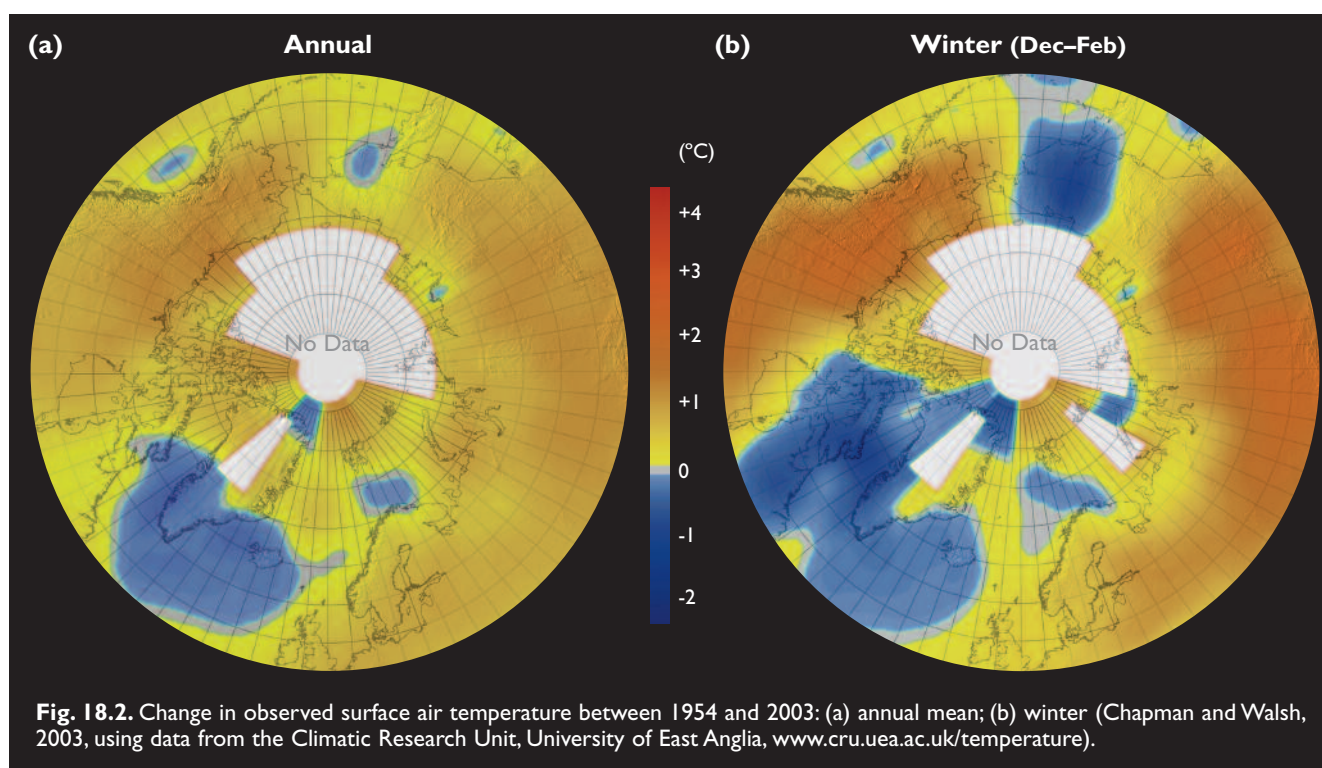
Fig. 18.2. Change in observed surface air temperature between 1954 and 2003: (a) annual mean; (b) winter (Chapman and Walsh, 2003, using data from the Climatic Research Unit, University of East Anglia, www.cru.uea.ac.uk/temperature).


Fig. 18.2. Owing to natural variations and the complex interactions of the climate system, the observed trends show variations within each region. Mean annual atmospheric surface temperature changes range from a 2 to 3 °C warming in Alaska and Siberia to a cooling of up to 1 °C in southern Greenland. Winter temperatures are up to 4 °C warmer in Siberia and in the western Canadian Arctic.

Although some regions have cooled slightly the overall trend for the Arctic is a substantial warming over the last few decades. For the Arctic as a whole, the 20th century can be divided into two warming periods, bracketing a 20-year cooling period (approximately 1945 to 1966) in the middle of the century. This pattern is less evident in northern Canada than in some other areas of the Arctic. The Canadian Archipelago and West Greenland did experience some cooling mid-century, although even then, there was substantial winter warming. The warming has been significant over the past few decades (1966 to 2003), particularly in the Northwest Territories – continuing the band of substantial warming across northwest North America that also covers Alaska and the Yukon – reaching an increase of 2 °C per decade. This warming is most evident in winter and spring. A more detailed description of observed climate change is given in Chapter 2. The climate change for each of the four ACIA regions is summarized in section 18.3.

Observations of arctic precipitation are restricted to a limited network of stations and are often unreliable since winter snowfall is not accurately measured by existing gauges, due to drifting snow. Available records indicate 20th-century increases in precipitation at high latitudes on the North American continent but little if any change in precipitation in the watersheds of the large Siberian rivers.

Rapid changes in regional climates (so-called regime shifts) are also evident in the climatic record. For example, in 1976 in the Bering Sea region there was a relatively sudden shift in prevailing climatic patterns, which included rapid warming and reduction in sea-ice extent. Such shifts have led to numerous, nearly instantaneous impacts on biota and ecosystems, as well as impacts on human communities and their interactions with the environment. Although such fluctuations are not fully understood and are therefore difficult to predict, regime shifts can be expected to continue to occur in the future, even as the baseline climate is also changing as a result of global warming (see section 18.4.3).

18.2.1.2. Indigenous observations of recent changes in climate

Indigenous observations of climate change, as discussed in Chapters 3 and 12, contribute to understanding of climate change and associated changes in the behavior and movement of animals. Through their various activities, which are closely linked to their surroundings, the indigenous peoples of the Arctic experience the climate in a very personal way. Over many generations and based on direct, everyday experience of living in the Arctic, they have developed specific ways of observing, interpreting, and adjusting to weather and climate changes. Based on careful observations, on which they often base life and death decisions and set priorities, indigenous peoples have come to possess a rich body of knowledge about their surroundings. Researchers are now working with indigenous peoples to learn from their observations and perspectives about the influences of climate change and weather events on the arctic environment and on their own lives and cultures. These studies are finding that the climate variations observed by

indigenous people and by scientific observation are, for the most part, in good accord and often provide mutually reinforcing information.

The presently observed climate change is increasingly beyond the range experienced by the indigenous peoples in the past. These new conditions pose new risks to the lifestyles of the indigenous populations, as described in section 18.2.2. The magnitude of these threats is critically dependent on the rate at which change occurs. If change is slow, adaptation may be possible; if however, change is rapid, adaptation is very likely to be considerably more difficult, if possible at all in response to some types of impacts.

Recent observations by the indigenous peoples of the Arctic of major changes in the climate and associated impacts are summarized in Table 18.1. Taken together, the body of observations from people residing across the Arctic presents a compelling account of changes that are increasingly beyond what their experience tells them about the past.

Indigenous observations of climate and related environmental changes include many other effects on plants and animals that are important to them (Chapter 7). These observations provide evidence of nutritional stresses on many animals that are indicative of a changing environment and changes in food availability. New species, never before recorded in the Arctic, have also been observed. The distribution ranges of some species of birds, fish, and mammals now extend further to the north than in the past. These observations are significant for indigenous

communities since changes likely to occur in traditional food resources will have both negative and positive impacts on the culture and economy of arctic peoples.

18.2.1.3. Projections of future climate

In projections of future climate, uncertainties of many types can arise, especially for as complex a challenge as projecting ahead 100 years. The ACIA adopted a lexicon of terms (section 1.3.3) describing the likelihood of expected change (Fig. 18.3). These terms are used throughout this chapter, and in all ACIA documents.

Chapter 4 presents the ACIA projections of future changes in arctic climate. These projections extend the IPCC assessment (IPCC, 2001) by presenting regional (north of 60º N) climate parameters, derived from global model outputs. The ACIA used five different global climate models (CGCM2, Canadian Centre for Climate Modelling and Analysis; CSM_1.4, National Center for Atmospheric Research, United States; ECHAM4/OPYC3, Max Planck Institute for Meteorology, Germany; GFDL-R30_c, Geophysical Fluid Dynamics Laboratory, United States; and HadCM3, Hadley Centre for Climate Prediction and Research, United Kingdom) forced with two different emissions (GHG and aerosol) scenarios. The emissions scenarios are the B2 and A2 scenarios drawn from the IPCC Special Report on Emissions Scenarios (Nakićenović and Swart, 2000). The A2 emissions scenario assumes global emphasis on sustained economic development while the B2 emissions scenario reflects a world that promotes environmental sustainability. Neither scenario is considered an upper or lower

Table 18.1. Examples of indigenous observations of environmental change in the Arctic. This table is mainly based on Chapters 3 and 12.

	European Arctic	Canada and Greenland	Alaska
Atmosphere/weather/winds	Weather patterns are changing so fast that traditional methods of prediction are no longer applicable. Winters are warmer. Seasonal patterns have changed.	Weather patterns are changing so fast that traditional methods of prediction are no longer applicable. Winters are warmer. There has been cooling in Hudson Strait/Baffin Island area, but greater variability.	Weather patterns are changing so fast that traditional methods of prediction are no longer applicable. There are more storms and fewer calm days. Winters are shorter and warmer, summers longer and hotter.
Rain/snow	Rain is more frequent in winter than before. There are more freeze–thaw cycles, thus more trouble for reindeer grazing in winter.	Snow is melting earlier and some permanent snow patches disappear. There is less snow and more wind, producing snow conditions that do not allow igloo building.	There is less snow.
Ocean/sea ice		Later freeze-up and earlier breakup of sea ice. Shore-fast ice is melting faster, creating large areas of open water earlier in summer.	Sea ice is thinner and is forming later. There is increased coastal erosion due to storms and lack of ice to protect the shoreline from waves.
Lakes/rivers/permafrost	Ice on lakes and rivers is thinner.	Water levels in lakes and rivers are falling on the Canadian mainland. Thinner river ice affects caribou on migration (they fall through). Permafrost is thawing, slumping soil into rivers and draining lakes.	Lakes and wetlands are drying out. Permafrost thawing is affecting village water supply, sewage systems, and infrastructure.
Plants and animals	New species are moving into the region.	Caribou suffer from more insects; body condition has declined. Caribou migration routes have changed.	Trees and shrubs are advancing into tundra. There are die-offs of seabirds and marine mammals due to poor body condition. New species of insects are observed.

Fig. 18.3. Five-tier lexicon describing the likelihood of expected change.

bound on possible levels of future emissions. The climatic and environmental changes in the Arctic projected using the two scenarios are similar through about 2040, but diverge thereafter, with projections forced with the A2 emissions scenario showing greater warming.

These projections are not intended to capture a large range of possible futures for the Arctic under scenarios of continuing emissions of GHGs and other pollutants. For practical reasons, only a limited number of future change scenarios could be developed for this assessment. Nonetheless, while the ACIA used only two different emissions scenarios, five global climate models were used to project change under the two emissions scenarios, capturing a good range of the uncertainty associated with how different models represent climate system processes.

Under the A2 and B2 emissions scenarios, the models projected that mean annual arctic surface temperatures north of 60° N will be 2 to 4 °C higher by mid-century and 4 to 7 °C higher toward the end of the 21st century (Fig. 18.4), compared to the present. Precipitation is projected to increase by about 8% by mid-century and by about 20% toward the end of the 21st century. There are differences among the projections from the different models, however. Although the projected trends are similar for the next few decades, the scatter of results for either the A2 or B2 emissions scenarios is about 2 to 3 °C toward the end of the 21st century. The reasons for this scatter are differences in the rep-

resentation of physical processes and feedbacks that are particularly important in the Arctic (e.g., changes in albedo due to reduced snow and ice cover, clouds, atmosphere–ocean interactions, ocean circulation), and natural variations that remain significant compared with the induced changes for at least the next few decades. While observations seem to indicate some increase in the frequency and severity of extreme events, these are very difficult to project.
Composite five-model projections for annual and winter mean surface air temperature changes in the Arctic between 1981–2000 and 2071–2090 using the B2 emissions scenario are shown in Fig. 18.5a (annual) and Fig. 18.5b (winter). Projected annual temperatures show a fairly uniform warming of 2 to 4 °C throughout the Arctic by the end of the century, with a slightly higher warming of up to 5 °C in the East Siberian Sea. Summer temperatures are projected to increase by 1 to 2 °C over land, with little change in the central Arctic Ocean, where sea ice melts each summer, keeping the ocean temperature close to 0 °C. Winter temperatures show the greatest warming: about 5 °C over land, and up to 8 to 9 °C in the central Arctic Ocean, where the feedback due to reduced sea-ice extent is largest. Regional and seasonal differences between the individual model results can be large, however, for the reasons previously discussed.

Changes in the Arctic affect the global system in several ways. Global climate change is influenced by feedback processes operating in the Arctic; these also amplify climate change in the Arctic itself. Apart from the well-known and often quoted ice- and snow-albedo feedback, another important arctic feedback is the thawing of permafrost, which is likely to lead to additional GHG releases. Arctic cloud feedbacks are also important but are still poorly understood. Some of these arctic feedbacks are adequately represented in general circulation models while others are not. Changes in the Arctic also affect the global system in other ways. Climate change is likely to increase precipitation throughout the Arctic and increase runoff to the Arctic Ocean; such a freshening is likely to slow the global thermohaline circulation with consequences for global climate. The melting of arctic glaciers and ice sheets is another effect of climate change that contributes to global sea-level rise with all its inherent problems. The global implications of these feedbacks are discussed in greater detail in section 18.2.2.

18.2.1.4. Ozone and UV radiation change

Atmospheric ozone is vital to life on earth. The stratosphere contains the majority of atmospheric ozone, which shields the biosphere by absorbing UV radiation from the sun. Anthropogenic chlorofluorocarbons are primarily responsible for the depletion of ozone in the stratosphere, particularly over the poles. Atmospheric dynamics and circulation strongly influence ozone

Fig. 18.4. Changes in surface air temperature north of 60° N between the 1981–2000 baseline and 2100 as projected by the five ACIA-designated models forced with the A2 and B2 emissions scenarios.

Fig. 18.5. (a) Projected annual surface air temperature change from the 1990s to the 2090s, based on the average change project-
ed by the five ACIA-designated climate models using the B2 emissions scenario. (b) Projected surface air temperature change in
winter from the 1990s to the 2090s, based on the average change projected by the five ACIA-designated climate models using the
B2 emissions scenario.

amounts over the poles, which in normal conditions tend
to be higher than over other regions on earth. During
conditions of ozone depletion, however, ozone over the
polar regions can be substantially reduced. This depletion
is most severe in the late winter and early spring, when
unperturbed ozone amounts are typically high. Ozone
losses over the Arctic are also strongly influenced by
meteorological variability and large-scale dynamical
processes. Winter temperatures in the polar stratosphere
tend to be near the threshold temperature for forming
polar stratospheric clouds, which can accelerate ozone
destruction, leading to significant and long-lasting deple-
tion events. Because climate changes due to increasing
GHGs are likely to lead to a cooling of the stratosphere,
polar stratospheric cloud formation is likely to become
more frequent in future years, causing episodes of severe
ozone depletion to continue to occur over the Arctic.

Decreases in stratospheric ozone concentrations are very
likely to lead to increased UV radiation levels at the sur-
face of the earth. Clouds, aerosols, surface albedo, alti-
tude, and other factors also influence the amount of UV
radiation reaching the surface. Achieving an accurate pic-
ture of UV radiation doses in the Arctic is complicated
by low solar elevations and by reflectance off snow and
ice. Ultraviolet radiation has long been a concern in the
Arctic, as indicated by protective goggles found in the
archaeological remains of indigenous peoples. Depletion
of ozone over the Arctic, as has been observed in several
years since the early 1980s, can lead to increased
amounts of UV radiation, particularly UV-B radiation,
reaching the surface of the earth, exposing humans and
ecosystems to higher doses than have historically been
observed. These higher doses are most likely to occur

during spring, which is also the time of year when many
organisms produce their young and when plants experi-
ence new growth. Because ecosystems are particularly
vulnerable to UV radiation effects during these stages,
increased UV radiation doses during spring could have
serious implications throughout the Arctic.

Chapter 5 discusses observed and projected changes in
atmospheric ozone and surface UV radiation levels.
Satellite and ground-based observations since the early
1980s indicate substantial reductions in ozone over the
Arctic during the late winter and early spring. Between
1979 and 2000, mean spring and annual atmospheric
ozone levels over the Arctic declined by 11 and 7%,
respectively. During the most severe depletion events,
arctic ozone losses of up to 45% have occurred.
Although international adherence to the Montreal
Protocol and its amendments is starting to lead to a
decline in the atmospheric concentrations of ozone-
depleting substances, ozone levels over the Arctic are
likely to remain depleted for the next several decades.
For the Arctic, most models project little recovery over
the next two decades. Episodes of very low spring
ozone levels are likely to continue to occur, perhaps
with increasing frequency and severity because of the
stratospheric cooling projected to result from increasing
concentrations of GHGs. These episodes of very low
ozone can allow more UV radiation to reach the earth's
surface, suggesting that people and ecosystems in the
Arctic are likely to be exposed to higher-than-normal
UV radiation doses for perhaps the next 50 years.

Table 18.2 summarizes some of the major aspects of
changes in ozone and UV radiation levels.

Table 18.2. Observed and projected trends in ozone and ultraviolet radiation levels and factors affecting levels of ultraviolet radiation in the Arctic. This table is mainly based on Chapter 5.

	Observed	Projected
Ozone and UV radiation trends	Combined satellite and ground-based observations indicate that mean spring and annual atmospheric ozone levels over the Arctic declined by 11 and 7%, respectively, between 1979 and 2000. These losses allowed more UV radiation to reach the surface of the earth. Individual measurements suggest localized increases in surface UV radiation levels, although high natural variability makes it difficult to identify a trend conclusively.	Future ozone levels over the Arctic are difficult to project, partly owing to the link with climate change. Current projections suggest that ozone over the Arctic is likely to remain depleted for several decades. This depletion would allow UV radiation levels to remain elevated for several decades. The elevated levels are likely to be most pronounced in spring, when many ecosystems are most sensitive to UV radiation exposure.
Low ozone episodes	Multi-week episodes of very low ozone concentration (depletion of 25 to 45%) have been observed in several springs since the early 1990s.	Decreasing stratospheric temperatures resulting from climate change may cause low ozone episodes to become more frequent.
Seasonal variations in ozone and UV radiation levels	There is high seasonal and interannual variability in arctic ozone levels, due to atmospheric processes that influence ozone production and distribution. Over the Arctic, stratospheric ozone levels are typically highest in late winter and early spring, when ozone depletion is most likely to occur. Surface UV radiation amounts vary with solar angle and day length throughout the year. In general, UV radiation doses are highest in summer, but can also be significant in spring due to ozone depletion combined with UV radiation enhancements from reflection off snow.	
Cloud effects	Cloud cover typically attenuates the amount of UV radiation reaching the surface of the earth. When the ground is snow-covered, this attenuation is diminished and UV radiation levels reaching the surface may increase due to multiple scattering between the surface and cloud base.	Future changes in cloud cover are currently difficult to project, but are likely to be highly regional.
Albedo effects	Changes in snow and ice extent affect the amount of UV radiation reflected by the surface. Reflection off snow can increase biologically effective UV irradiance by over 50%. In addition, high surface albedo affects UV radiation amounts incident on vertical surfaces more strongly than amounts incident on horizontal surfaces. Snow-covered terrain can substantially enhance UV radiation exposure to the face or eyes, increasing cases of snow blindness and causing potential long-term skin or eye damage.	Climate changes are likely to alter snow cover and extent in the Arctic. Reduced snow and ice cover means less reflection of UV radiation, decreasing the UV radiation levels affecting organisms above the snow.
Snow and ice cover	Snow and ice cover shields many arctic ecosystems from UV radiation for much of the year.	Climate changes are likely to alter snow cover and extent in the Arctic. Reduced snow and ice cover will increase the UV radiation levels experienced by organisms that would otherwise be shielded by snow or ice cover.
Impacts of increased UV radiation levels	Ultraviolet radiation effects on organisms in human health and on terrestrial and aquatic ecosystems include skin cancer, corneal damage, immune suppression, sunburn, snow blindness. Ultraviolet radiation also damages wood, plastics, and other materials widely used in arctic infrastructure.	All the impacts noted in the "Observed" column are likely to worsen.

18.2.2. Arctic-wide impacts

18.2.2.1. Impacts on the environment

Changes in snow, ice, and permafrost

Recent observational data, discussed in detail in Chapter 6, present a generally consistent picture of cryospheric variations that are shaped by patterns of recent warming and variations in atmospheric circulation. Consistent with the overall increase in global temperatures, arctic snow and ice features have diminished in extent and volume. While the various cryospheric and atmospheric changes are consistent in an aggregate sense and are

quite large in some cases, it is possible that natural, low-frequency variations in the atmosphere and ocean have played at least some role in forcing the cryospheric and hydrological trends of the past few decades.

Model projections of anthropogenic climate change indicate a continuation of the recent trends through the 21st century, although the rates of the projected changes vary widely due to differences in model representations of feedback processes. Models project a 21st-century decrease in sea-ice extent of up to 100% in summer; a widespread decrease in snow-cover extent, particularly in spring and autumn; and permafrost degradation over 10 to 20% of the present permafrost

area and a movement of the permafrost boundary northward by several hundred kilometers. The models also project river discharge increases of 5 to 25%; earlier breakup and later freeze-up of rivers and lakes; and a sea-level rise of several tens of centimeters resulting from glacier melting and thermal expansion, which is amplified or reduced in some areas due to long-term land subsidence or uplift.

Table 18.3 summarizes observed and projected trends in the snow and ice features of the Arctic, including snow cover, glaciers, permafrost, sea ice, and sea-level rise. Because the snow and ice features of the Arctic are not only sensitive indicators of climate change but also play a crucial role in shaping the arctic environment, any changes in these features are very likely to have profound effects on the environment, biota, ecosystems, and humans.

Changes on land

Climate change is also likely to have profound effects on the tundra and boreal forest ecosystems of the Arctic. Arctic plants, animals, and microorganisms adapted to climate change in the past primarily by relocation, and their main response to future climate change is also like-

ly to be relocation. In many areas of the Arctic, however, relocation possibilities are likely to be limited by regional and geographical barriers. Nevertheless, changes are already occurring in response to recent warming. Chapters 7, 8, and 14 provide details of the major conclusions presented here.

Some arctic species, especially those that are adapted to the cold arctic environment (e.g., mosses, lichens, and some herbivores and their predators) are especially at risk of loss in general, or displacement from their present locations. Present species diversity is more at risk in some ACIA regions than others; for example, Beringia (Region 3) has a higher number of threatened plant and animal species than any other ACIA region. While there will be some losses in many arctic areas, movement of species into the Arctic is likely to cause the overall number of species and their productivity to increase, thus overall biodiversity measured as species richness is likely to increase along with major changes at the ecosystem level.

Freshwater systems in the Arctic will also be affected due to changes in river runoff, including the timing of runoff from thawing permafrost, and changes in river-

Table 18.3. Observed and projected trends for the arctic cryosphere. This table is mainly based on Chapter 6.

	Observed	Projected for the 21st century
Snow cover	Snow-cover extent in the Northern Hemisphere has decreased by 5 to 10% since 1972; trends of such magnitude are rare in GCM simulations.	Snow-cover extent is projected to decrease by about 13% by 2071–2090 under the projected increase in mean annual temperature of about 4 °C. The projected reduction is greater in spring. Owing to warmer conditions, some winter precipitation in the form of rain is likely to increase the probability of ice layers over terrestrial vegetation.
Glaciers	Glaciers throughout the Northern Hemisphere have shrunk dramatically over the past few decades, contributing about 0.15 to 0.30 mm/yr to the average rate of sea-level rise in the 1990s.	The loss of glacial mass through melting is very likely to accelerate throughout the Arctic, with the Greenland Ice Sheet also starting to melt. These changes will tend to increase the rate of sea-level rise.
Permafrost	Permafrost temperatures in most of the Arctic and subarctic have increased by several tenths of a degree to as much as 2 to 3 °C (depending on location) since the early 1970s. Permafrost thawing has accompanied the warming.	Over the 21st century, permafrost degradation is likely to occur over 10 to 20% of the present permafrost area, and the southern limit of permafrost is likely to move northward by several hundred kilometers.
Sea ice	Summer sea-ice extent decreased by about 7% per decade between 1972 and 2002, and by 9% per decade between 1979 and 2002, reaching record low levels in 2002. The extent of multi-year sea ice has also decreased, and ice thickness in the Arctic Basin has decreased by up to 40% since the 1950s and 1960s due to climate-related and other factors.	Sea-ice extent is very likely to continue to decrease, particularly in summer. Model projections of summer sea-ice extent range from a loss of several percent to complete loss. As a result, the navigation season is projected to be extended by several months.
River discharge	River discharge has increased over much of the Arctic during the past few decades and the spring discharge pulse is occurring earlier.	Models project that total river discharge is likely to increase by an additional 5 to 25% by the late 21st century.
Breakup and freeze-up	Earlier breakup and later freeze-up of rivers and lakes across much of the Arctic have lengthened the ice-free season by 1 to 3 weeks.	The trend toward earlier breakup and later freeze-up of rivers and lakes is very likely to continue, consistent with increasing temperature. Breakup flooding is likely to be less severe.
Sea-level rise	Global average sea level rose between 10 and 20 cm during the 20th century. This change was amplified or moderated in particular regions by tectonic motion or isostatic rebound.	Models project that glacier contributions to sea-level rise will accelerate in the 21st century. Combined with the effects of thermal expansion, sea level is likely to rise by 20 to 70 cm (an average of 2 to 7 mm/year) by the end of the 21st century.

and lake-ice regimes. Changes in water flows as permafrost thaws are very likely to alter the biogeochemistry of many areas and create new wetlands and ponds, connected by new drainage networks. More water will alter the winter habitats in freshwater systems and increase survival of freshwater and sea-run fish. On hill slopes and higher ground, permafrost thawing is likely to drain and dry existing soils and wetlands. The productivity of these systems is likely to increase, as well as species diversity.

Table 18.4. Projected impacts on terrestrial ecosystems. This table is mainly based on Chapter 7.

	Projected impact
Ecotone transitions	Warming is very likely to lead to slow northward displacement of tundra by forests, while tundra will in turn displace high-arctic polar desert. Tundra is projected to decrease to its smallest extent in the last 21 000 years. In dry areas where thawing permafrost leads to drainage of the active layer, forests are likely to be replaced by tundra–steppe communities. Where thawing permafrost leads to waterlogging, forest will be displaced by bogs and wetlands.
Forest changes	Forests are likely to expand and in some areas, where present-day tundra occupies a narrow zone, are likely to reach the northern coastline. The expansion will be slowed by increased fire frequency, insect outbreaks, and vertebrate herbivory, as has already been observed in some parts of the Arctic.
Species diversity	Climate warming is very likely to lead to northward extension of the distribution ranges of species currently present in the Arctic and to an increase in the total number of species. Individual species will move at different rates and new communities of associated species are likely to form. Climate warming is also likely to lead to a decline or extirpation of populations of arctic species at their southern range margins. As additional species move in from warmer regions, the number of species in the Arctic and their productivity are very likely to increase.
Species at risk	Specialist species adapted to the cold arctic climate, ranging from mosses, lichens, vascular plants, some herbivores (lemmings and voles) and their predators, to ungulates (caribou and reindeer), are at risk of marked population decline or extirpation locally. This will be largely as a consequence of their inability to compete with species invading from the south. The biodiversity in Beringia is at risk as climate warms since it presently has a higher number of threatened plant and animal species than any other arctic region.
UV radiation effects	Increased UV radiation levels resulting from ozone depletion are likely to have both short- and long-term impacts on some ecosystem processes, including reduced nutrient cycling and decreased overall productivity. Many arctic plant species are assumed to be adaptable to high levels of UV-B radiation. Adaptation involves structural and chemical changes that can affect herbivores, decomposition, nutrient cycling, and productivity.
Carbon storage and fluxes	Over the long term, replacement of arctic vegetation with more productive southern vegetation is likely to increase net carbon storage in ecosystems, particularly in regions that are now tundra or high-arctic polar desert. Methane fluxes are likely to increase as vegetation grows in tundra ponds, and as wetlands become warmer (until they dry out). Methane fluxes are also likely to increase when permafrost thaws.
Albedo feedback	The positive feedback of albedo change (due to forest expansion) on climate is likely to dominate over the negative (cooling) feedback from an increase in carbon storage. The albedo reduction due to reduced terrestrial snow cover will be a major additional feedback.

Table 18.5. Projected impacts on freshwater ecosystems. This table is mainly based on Chapter 8.

	Projected impact
Lakes	Reduced ice cover and a longer open-water season are very likely to affect thermal regimes, particularly lake stratification. Permafrost thaw in ice-rich environments is very likely to lead to catastrophic lake drainage; increased groundwater flux will drain other lakes. A probable decrease in summer water levels of lakes and rivers is very likely to affect the quality and quantity of, and access to, aquatic habitats.
Rivers	A likely shift to less intense ice breakup will reduce the ability of flow systems to replenish riparian ecosystems, particularly in river deltas. Reduced climatic gradients along large northern rivers are likely to alter ice-flooding regimes and related ecological processes. A very likely increase in winter flows and reduced ice-cover growth will increase the availability of under-ice habitats.
Water quality	Enhanced permafrost thawing is very likely to increase nutrient, sediment, and carbon loadings to aquatic systems, with a mixture of positive and negative effects on freshwater chemistry. An earlier phase of enhanced sediment supply will probably be detrimental to benthic fauna but the balance will be ecosystem- or site-specific. Freshwater biogeochemistry is very likely to alter following changes in water budgets.
Wetlands	Changes in climate are very likely to lead to an increased extent of wetlands, ponds, and drainage networks in low-lying permafrost-dominated areas, but also to losses of wetlands on hill slopes and higher ground. Coastal erosion and inundation will generate new wetlands in some coastal areas. Conversely, increased evapotranspiration is likely to dry peatlands, particularly during the warm season.
Species diversity	Changes in the timing of freshwater habitat availability, quality, and suitability are very likely to alter the reproductive success of species. Correspondingly, the rate and magnitude of climate change and its effects on aquatic systems are likely to outstrip the capacity of many aquatic biota to adapt or acclimate. Climate change is very likely to act cumulatively and/or synergistically with other stressors to affect the overall biodiversity of aquatic ecosystems.
UV radiation effects	Reduced ice cover in freshwater ecosystems is likely to have a greater effect on underwater UV radiation exposure than projected levels of stratospheric ozone depletion. Little is known about the adaptive responses of aquatic organisms to changing UV radiation levels.

Changes in animal and plant populations are often triggered by extreme events, particularly winter processes. Weather extremes in winter are likely to have greater effects on the mammals and birds that remain active in winter, than on plants, insects, and other invertebrates that are dormant in winter. While some projections indicate a likely increase in the frequency and severity of extreme events (storms, floods, icing of snow layers, drought) the distribution of these events is very difficult to project. Rapid changes present additional stresses if they exceed the ability of species to adapt or relocate since they are likely to lead to increased incidence of fires, disease, and insect outbreaks, as well as to restricted forage availability.

The impact of changes in climate and UV radiation levels on species and ecosystems is likely to make the current use of many protected areas as a conservation practice almost obsolete. Although local measures to reduce hunting quotas might moderate impacts of climate change on wildlife species, habitat protection requires a new, more flexible paradigm. Comparison of areas in the Arctic in which vegetation is likely to dramatically change with the location of current protected areas shows that many habitats will be altered so that they will no longer serve to support the intended species or communities. These impacts will be reduced if simple measures are incorporated into the design of protected areas, for example, designating flexible boundaries that encompass extended latitudinal tracts of land and protect corridors for species movement.

As warming allows trees to grow, forests are projected to replace a significant proportion of the tundra.

This process is very likely to be slowed locally by natural barriers to movement, human activities, fires, insect attacks, browsing by vertebrate herbivores, and drying or waterlogging of soils, but the long-term effect on species composition will be significant. Displacement of tundra by forest will also lead to a decrease in albedo, which will increase the positive (warming) feedback to the climate system, especially during spring when snow melts, and amplify changes in the local climate. Warming and drying of tundra soils are likely to lead to an increased release of carbon, at least in the short term. However, current models suggest that the Arctic may become a net sink for carbon (although the uncertainties associated with the projections are high). There are also uncertainties about changes in methane (CH_4) fluxes (although current CH_4 emissions from arctic ecosystems are already forcing climate) from wetlands, permafrost, and CH_4 hydrates, so it is not known if the circumpolar tundra will become a carbon sink or carbon source in the long term.

Tables 18.4 and 18.5 summarize the most important impacts projected for terrestrial and freshwater ecosystems, respectively.

Changes in the ocean

Through its influence on the Atlantic thermohaline circulation, the Arctic plays a critical part in driving the global thermohaline circulation. It is possible that increased precipitation and runoff of fresh water and the melting of glaciers and ice sheets, and thawing of the extensive permafrost underlying northern Siberia, could

Table 18.6. Projected impacts in the Arctic Ocean and subarctic seas. This table is mainly based on Chapters 9 and 13.

	Projected impact
Ocean regime	Increased runoff from major arctic rivers and increased precipitation over the Arctic Ocean are very likely to decrease its salinity.
Thermohaline circulation	A slow-down of the global thermohaline circulation is likely as a result of increased freshwater input from melting glaciers and precipitation. This is likely to delay warming for several decades in the Atlantic sector of the Arctic as a result of reduced ocean heat transport.
Sea-ice regime	All the ACIA-designated models project substantial reductions in sea-ice extent and likely opening of the Northern Sea Route to shipping during summer. Some of the models project an entirely ice-free Arctic Ocean in summer by the end of the 21st century. Greater expanses of open water will also increase the positive feedback of albedo change to climate.
Marine ecosystems	Reduced sea-ice extent and more open water are very likely to change the distribution of marine mammals (particularly polar bears, walrus, ice-inhabiting seals, and narwhals) and some seabirds (particularly ivory gulls), reducing their populations to vulnerable low levels. It is likely that more open water will be favorable for some whale species and that the distribution range of these species is very likely to spread northward.
UV radiation effects	Ultraviolet radiation can act in combination with other stressors, including pollutants, habitat destruction, and changing predator populations, to adversely affect a number of aquatic species. In optically clear ocean waters, organisms living near the surface are likely to receive harmful doses of UV radiation. Sustained, increased UV radiation exposure could also have negative impacts on fisheries.
Fisheries	Changes in the distribution and migration patterns of fish stocks are likely. It is possible that higher primary productivity, increases in feeding areas, and higher growth rates could lead to more productive fisheries in some regions of the Arctic. New species are moving into the Arctic and competing with native species. The extinction of existing arctic fish species is unlikely.
Coastal regions	Serious coastal erosion problems are already evident in some low-lying coastal areas, especially in the Russian Far East, Alaska, and northwestern Canada, resulting from permafrost thawing and increased wave action and storm surges due to reduced sea-ice extent and sea-level rise. Ongoing or accelerated coastal-erosion trends are likely to lead to further relocations of coastal communities in the Arctic.

freshen arctic waters, causing a reduction in the over-turning circulation of the global ocean and thus affecting the global climate system and marine ecosystems. The IPCC 2001 assessment considers a future reduction of the Atlantic thermohaline circulation as likely, while a complete shutdown is considered as less likely, but not impossible. If half the oceanic heat flux were to disappear with a weakened Atlantic inflow, then the associated cooling would more than offset the projected heating in the 21st century. Thus, there is the possibility that some areas in the Atlantic Arctic will experience significant *regional* cooling rather than warming, but the present models can assess neither its probability, nor its extent and magnitude.

The most important projected trends for the marine systems of the Arctic are summarized in Table 18.6.

18.2.2.2. Impacts on people's lives

Several chapters address the impacts of climate change on people, including Chapters 10, 11, 12, 14, 15, and 16. The Arctic is home to a large number of distinct groups of indigenous peoples and the populations of eight nations. Between two and four million indigenous and non-indigenous people live in the Arctic, depending on how the Arctic is defined. Most live in cities; in Russia

large urban centers include Vorkuta and Norilsk with populations listed as exceeding 100 000, and Murmansk with about 500 000 people, although the population of these cities has decreased in recent years. Arctic towns in Scandinavia and North America are smaller; Reykjavik has around 110 000 inhabitants and Rovaniemi about 65 000. In total there are probably around 30 towns in the Arctic with more than 10 000 inhabitants.

Table 18.7 summarizes the projected social impacts of climate change and UV radiation on the people of the Arctic. Climate change is only one, and perhaps not the most important, factor currently affecting people's lives and livelihood in the Arctic. For example, the people living in Russia's Far North have experienced dramatic political, social, and economic changes since the collapse of the former Soviet Union; and Europeans, Canadians, and Alaskans have experienced major changes resulting from the discovery of minerals, oil and gas reserves, and the declines or increases of some of the northern fisheries.

For the indigenous population, and particularly for those people who depend on hunting, herding, and fishing for a living, climate change is likely to be a matter of cultural survival, however. Their uniqueness as people with cultures based on harvesting marine mammals, hunting,

Table 18.7. Projected social impacts on arctic residents. This table is mainly based on Chapters 12, 15, and 16.

	Projected impact
Impacts on arctic residents	
Infrastructure	Permafrost thawing is very likely to threaten buildings, roads, and other infrastructure. This includes increases in the settling and breaking of underground pipes and other installations used for water supply, heating systems, and waste disposal, and threats to the integrity of containment structures such as tailing ponds and sewage lagoons.
Water	While increased river runoff is projected to occur mainly in winter and spring, lower water tables in rivers and lakes in summer will reduce available water and impede river travel in some areas (e.g., the Mackenzie River watershed).
Health	Circumpolar health problems such as those associated with changes in diet and UV radiation levels are likely to become more prominent. Increases in zoonotic diseases and injury rates are likely, due to environmental changes and climate variability.
Income	Impacts on the economy are expected as a consequence of climate change in the Arctic and will affect work opportunities and income of arctic residents. Expected increases in productivity and greater opportunity for settlement are also likely to benefit people within and beyond the region.
Impacts specific to indigenous communities	
Food security	Obtaining and sharing traditional foods, both cultural traditions, are very likely to become more difficult as the climate changes, because access to some food species will be reduced. The consequences of shifting to a more Western diet are likely to include increased incidence of diabetes, obesity, and cardiovascular diseases. Food from other sources may also be more costly.
Hunting	Hunter mobility and safety and the ability to move with changing distribution of resources, particularly on sea ice, are likely to decrease, leading to less hunting success. Similarly, access to caribou by hunters following changed snow and river-ice conditions is likely to become more difficult. Harvesting the threatened remaining populations of some marine mammals could accelerate their demise.
Herding	Changing snow conditions are very likely to adversely affect reindeer and caribou herding (e.g., ice layers and premature thawing will make grazing and migration difficult and increase herd die-offs). Shorter duration of snow cover and a longer plant growth season, on the other hand, are likely to increase forage production and herd productivity if range lands and stocking levels are adequately managed.
Cultural loss	For many Inuit, climate change is very likely to disrupt or even destroy their hunting culture because sea-ice extent is very likely to be reduced and the animals they now hunt are likely to decline in numbers, making them less accessible, or they may even disappear from some regions. Cultural adaptation to make use of newly introduced species may occur in some areas.

herding caribou and reindeer, or fishing, is at risk because climate change is likely to deprive them of access to their traditional food sources, although new species, as they move north, may become available in some regions. Indigenous peoples have adapted to changes in the past through careful observations and skillful adjustments of their traditional activities and lifestyles, but the addition of climate and UV radiation changes and impacts on existing social, political, and other environmental stresses is already posing serious challenges. Today, the indigenous peoples live in greatly circumscribed social and economic situations and their hunting and herding activities are determined to a large extent by resource management regimes and local, regional, and global economic market situations that reduce their ability to adapt and cope with climate variability and change. While they experience stress from other sources that threatens their lifestyles and cultures, climate change magnifies these threats.

Improvements in human health are very likely to continue through advances in technology, but the potential for emerging diseases (via the introduction of new insect and animal vectors) in northern communities makes it difficult to project how climate change is likely to affect the overall health of arctic residents. Several types of impacts seem likely. Because it will be more difficult to access marine animals when hunting, and because there is greater danger to the hunters when traveling over thinner sea ice, and in open water in less predictable weather conditions, direct health effects through a changing diet and increased accident rates are likely. Increased UV radiation levels are also likely to directly affect health, increasing incidences of skin cancer, cataracts, and viral infections, owing to effects on the immune system. Studies by the World Health Organization estimate that a person receives the majority of their lifetime UV radiation exposure before 18 years of age. An entire generation of people in the

Table 18.8. Projected impacts on important economic activities in the Arctic. This table is mainly based on Chapters 13, 14, and 16, but also draws information from other chapters.

	Projected impact
Non-renewable resources	
Oil and gas	
Exploration	Reduced sea ice is likely to facilitate some offshore operations but hamper winter seismic work on shore-fast ice. Later freeze-up and earlier melting are likely to limit the use of ice and snow roads.
Production	Reduced extent and thinner sea ice are likely to allow construction and operation of more economical offshore platforms. Storm surges and sea-level rise are likely to increase coastal erosion of shore facilities and artificial islands. The costs of maintaining infrastructure and minimizing environmental impacts are likely to increase as a result of thawing permafrost, storm surges, and erosion.
Transportation	Reduced extent and duration of sea and river ice are likely to lengthen the shipping season and shorten routes (including trans-polar routes). Permafrost thawing is likely to increase pipeline maintenance costs.
Coal and minerals	
Production	The costs of maintaining infrastructure and minimizing environmental impacts are likely to increase as a result of thawing permafrost, storm surges, and erosion.
Transportation	Reduced extent and duration of sea ice are likely to lengthen the shipping season. Thawing permafrost is likely to affect roads and infrastructure.
Renewable resources	
Fish, shellfish, freshwater fish	
Fish stocks	Temperature, currents, and salinity changes are likely to lead to changes in species availability (positive in some areas, negative in others).
Harvests	Changes in migration patterns are likely to lead to changes in distances to fishing grounds, and possible relocation of processing plants. Increased storms, and icing of ship superstructure are likely to increase risks and reduce catches.
Timber	Productivity is likely to increase if there is adequate soil moisture but decrease if there are summer droughts. Fire and insect outbreaks are likely to decrease productivity.
Agricultural products	A warmer climate is likely to lengthen the growing season and extend the northern range of agriculture. Increased insect problems are likely to decrease productivity.
Energy	
Hydropower	Precipitation changes are likely to affect the water supply. Melting glaciers are likely to reduce future seasonal water supply.
Power lines	Icing events, storms, and ground thaw are likely to affect power lines.
Wildlife	
Harvests	Changes in distribution and migration patterns are likely to affect access to wildlife and change harvests. Invasive species are likely to compete with existing populations.
Conservation	Habitat loss, longer seasons, and boat access are likely to lead to over-harvesting in protected areas and affect conservation.

Arctic is likely to continue to be exposed to above-normal UV radiation levels, and a new generation will grow to adulthood under increased UV radiation levels. Although behavioral adaptations can reduce the expected impacts, adequate information and education about these effects must be available.

18.2.2.3. Impacts on the economy

The three most important sectors of the commercial economy of the Arctic are oil and gas, fish, and minerals, each of which will be influenced by changes in the climate. There are also other economic sectors that will be affected by climate change, including forestry, agriculture, and tourism. Impacts on industry and commerce are described in greater detail in Chapters 13, 14, and 16. The use of local resources for traditional purposes, including fish, wildlife, plants, and wood for fuel and home construction, are also part of the arctic economy and have been addressed in Chapters 11, 12, and 17.

Oil and gas

The Arctic has large oil and gas reserves. Most are located in Russia: oil in the Pechora Basin, gas in the Lower Ob Basin, and other potential oil and gas fields along the Siberian coast. In Siberia, oil and gas development has expanded dramatically over the past few decades, and this region produces 78% of Russia's oil and 84% of its natural gas. Canadian oil and gas fields are concentrated in two main basins in the Mackenzie Delta/Beaufort Sea region and in the high Arctic. Oil and gas fields also occur in other arctic waters, for example the Barents Sea. The oil fields at Prudhoe Bay, Alaska, are the largest in North America, and by 2002, around 14 billion barrels had been produced at this site. There are also substantial reserves of natural gas and coal along the North Slope of Alaska. The Arctic is an important supplier of oil and gas to the global economy. Climate change impacts on the exploration, production, and transportation activities of this industry could have both positive and negative market and financial effects. These are summarized in Table 18.8.

Fish

The arctic seas contain some of the world's oldest and most productive commercial fishing grounds. In the Northeast Atlantic and the Bering Sea and Aleutian region, annual fish harvests in the past have exceeded two million tonnes in each of the two regions. In the Bering Sea, overall harvests have remained stable at about two million tonnes, but while some species like pollock (*Theragra chalcogramma*) are doing well, others like snow crab (*Chionoecetes opilio*) have declined. Important fisheries also exist around Iceland, Greenland, the Faroe Islands, and Canada. Fisheries are important to many arctic countries, as well as to the world as a whole. For example, Norway is one of the world's biggest fish exporters with exports worth US$ 4 billion in 2001. In some arctic regions aqua-culture is a growing industry, providing local communities with jobs and income. Freshwater fisheries are also important in some areas. Changes in climatic conditions are likely to have both positive and negative financial impacts (see Table 18.8).

Minerals

The Arctic has large mineral reserves, ranging from gemstones to fertilizers. Russia extracts the greatest quantities of these minerals, including nickel, copper, platinum, apatite, tin, diamonds, and gold, mostly on the Kola Peninsula but also in the northern Ural Mountains, the Taymir region of Siberia, and the Far East. Canadian mining in the Yukon and Northwest Territories and Nunavut is for lead, zinc, copper, gold, and diamonds. In Alaska, lead and zinc are extracted at the Red Dog Mine, which sits atop two-thirds of US zinc resources, and gold mining continues in several areas. Coal mining occurs in several areas of the Arctic. Mining activities in the Arctic are an important contributor of raw materials to the global economy and are likely to expand with improving transportation conditions to bring products to market, due to a longer ice-free shipping season (Table 18.8).

Transportation industry

The cost of transporting products and goods into and out of the Arctic is a major theme of the potential impacts of climate change on many of the economic sectors described above. While climate change will affect many different modes of transport in the Arctic, the likelihood of reduced extent and duration of sea ice in the future will have a major impact. The projected opening of the Northern Sea Route (the opening of the Northwest Passage is less certain) to longer shipping seasons (Chapter 16) will provide faster and therefore cheaper access to the Arctic, as well as the possibility of trans-arctic shipping. This will provide new economic opportunities, as well as increased risks of oil and other pollution along these routes. Other regions of the Arctic will also benefit from easier shipping access due to less sea ice.

Projected climate-related impacts on the major economic sectors in the Arctic are listed in Table 18.8. This is a qualitative assessment only, since detailed financial estimates of economic impacts are not available at present, except in very few instances. Over the 21st century, new types of activities could arise (for example trans-arctic shipping) but there are likely to be others. This analysis focuses on how future climate change could affect the present economy, and is not based on projections of economic and demographic development in the Arctic over the 21st century.

Forestry, agriculture, and tourism

Forestry is an important economic activity in six of the eight arctic countries, and agriculture in its various forms also contributes to local economies in all eight countries. The basis for agricultural activities varies

throughout the Arctic. In North America, the limited agriculture helps to meet the need for local fresh produce during the short summer. In northern Europe and across the Russian North, crop production along with reindeer husbandry and some other domestic livestock production serve traditional cultural needs and provide opportunities for income. Tourism is also becoming an increasingly important economic factor in many arctic regions. Impacts on these economic sectors in monetary terms are difficult to project and quantify since factors other than climate, including future regional economic development, play a major role.

Wildlife

Arctic wildlife resources support communities throughout the Arctic, through whaling, fishing, and hunting, and wildlife contributes to both the monetary and traditional economies of the Arctic. Climate change threatens the culture and traditional lifestyles of indigenous communities but is not discussed here. Likely economic impacts due to climate change are relevant here but are not easily quantified at present.

18.3. A synthesis of projected impacts in the four regions

This section examines impacts within a more regional setting. A spatial division is necessary because the Arctic is very large and different regions are likely to experience patterns of climate change in the coming decades that are significantly different. Different regions of the Arctic are also distinguished by different social, economic, and political systems, which will mediate the impacts of and responses to climate change. These distinctions are captured broadly by the four regions defined in this assessment (see Fig. 18.6).

Fig. 18.6. The four regions of the Arctic Climate Impact Assessment.

Differences in large-scale weather and climate-shaping factors were primary considerations in selecting the four regions. Observations also indicate that the climate is presently changing quite differently in each of these regions, and even within them, especially where there are pronounced variations in terrain, such as mountains versus coastal plains. There are also large north–south gradients in climate variability within each region. The scale was thought to be roughly appropriate given that a larger number of smaller regions would not have been practical for this assessment, or compatible with a focus at the circumpolar level.

Region 1 includes East Greenland, northern Scandinavia, and northwestern Russia, as well as the North Atlantic with the Norwegian, Greenland, and Barents Seas. This region is projected to experience similar types of changes because the entire area is under the influence of North Atlantic atmospheric and oceanic conditions, particularly the Icelandic Low.

Region 2 includes Central Siberia, from the Urals to Chukotka, and the Barents, Laptev, and East Siberian Seas. This region represents the coldest part of the Arctic and is under the influence of the Siberian high-pressure system during winter.

Region 3 includes Chukotka, Alaska, the western Canadian Arctic to the Mackenzie River, and the Bering, Chukchi, and Beaufort Seas. This region is largely under the influence of North Pacific atmospheric and oceanic processes and the Aleutian Low.

Region 4 includes the central and eastern Canadian Arctic east of the Mackenzie River, the Queen Elizabeth Islands south to Hudson Bay, and the Labrador Sea, Davis Strait, and West Greenland. The region's weather systems are connected to large-scale North American and western North Atlantic weather patterns.

Major impacts due to observed and projected climate change for each of the four regions are summarized in sections 18.3.1 to 18.3.4. Details, including relevant references and publications on earlier impact assessments in the four regions, can be found in the preceding 17 chapters. The previous regional impact assessments were useful source material and laid a critical foundation for the ACIA. Some impacts apply to more than one or to all of the regions; such impacts are described in section 18.2 and are not necessarily listed separately for each region.

While the importance of providing information at the regional level has been emphasized here, the focus of the ACIA was at the circumpolar scale. The following sections attempt to synthesize significant findings for each of the four regions where these have been provided by the relevant chapters of the assessment. In some cases, the evaluated literature did not support a very extensive assessment of the nature of changes in the four regions.

Table 18.9. Key consequences of climate change on the environment, the economy, and on people's lives in the four ACIA regions. Unless otherwise stated these key consequences are considered likely to occur.

	Environment	Economy	People's lives
Region 1 Eastern Greenland, North Atlantic, northern Scandinavia, northwestern Russia	• Northward shifts in the distribution ranges of plant and animal species (terrestrial, freshwater, and marine) • Many tundra areas disappear from the mainland, except in arctic Russia where bog growth prevents forest development • Carbon storage increases and albedo decreases, but less so than in other regions	• Change in the location of North Atlantic and Arctic fisheries due to warmer waters and change in yields of many commercial fish stocks • Improved access to oil, gas, and mineral resources in presently ice-covered waters and adjacent land areas • Rising sea level and more storm surges affect coastal facilities	• Reduced and changing snow cover, affecting reindeer herding and hunted wildlife • Traditional harvest of animals is riskier and less predictable • Emergence of zoonotic diseases as a threat to human health • Increased outdoor leisure and recreational opportunity, plus lower heating costs
Region 2 Siberia	• Northward shifts in the distribution ranges of plant and animal species (terrestrial, freshwater, and marine) • Changing forest character due to warmer climate and permafrost thawing, with possibly greater fire and pest threats • Tundra changing to shrub and forest, but northern tundra extension limited by the ocean • Increased river discharge, affecting sediment and nutrient fluxes	• Reopening of the Northern Sea Route (Northeast Passage), due to reduced extent and duration of sea ice, providing new economic possibilities, and also increased pollution risks (tankers) • Improved access to oil, gas, and mineral resources in presently ice-covered waters and adjacent land areas • Rising sea level and more storm surges affect coastal facilities	• Permafrost thawing, causing serious damage to buildings in Siberian cities and to houses and facilities in villages • Traditional harvest of animals is riskier and less predictable • Emergence of zoonotic diseases as a threat to human health • Lower heating costs
Region 3 Chukotka, Bering Sea, Alaska, western Canadian Arctic	• Northward shifts in the distribution ranges of plant and animal species (terrestrial, freshwater, and marine) • Forest disruption due to warming and increased pest outbreaks • Reduced sea ice and general warming, disrupting polar bears, marine mammals, and other wildlife • Low-lying coastal areas more frequently inundated by storm surges and sea-level rise	• Damage to infrastructure due to thawing permafrost • Improved access to oil, gas, and mineral resources in presently ice-covered waters and adjacent land areas • Change in recruitment, growth rates, abundance, and distribution of Bering Sea fish due to warmer waters • Rising sea level and storm surges, affect coastal facilities	• Retreating sea ice and earlier snowmelt, altering traditional lifestyle patterns and food security, increasing risks taken by hunters, further stressing nutritional status • Coastal erosion and flooding forcing relocation of villages • Emergence of zoonotic diseases as a threat to human health • Increased outdoor leisure and recreational opportunity, plus lower heating costs
Region 4 Central and Eastern Canadian Arctic, Labrador Sea, Davis Strait, West Greenland	• Thawing of warm permafrost and reduced river and lake ice, changing hydrological regimes • Northward shifts in the distribution ranges of plant and animal species (terrestrial, freshwater, and marine) • High-arctic polar desert replaced by tundra in some areas, leading to potential large carbon gains • Increased melting of the Greenland Ice Sheet, changing the coastal environment • Decreasing sea-ice extent; threatening the extinction of polar bears	• Potential increased shipping in the Northwest Passage as sea ice retreats, providing economic incentives such as cheaper transport of goods, but also increasing pollution and oil-spill risks • Shorter operating season for ice and snow roads • Changes in marine and freshwater fisheries with impacts on tourism and local economic development • Rising sea level and storm surges affect coastal facilities	• Traditional lifestyles and survival of indigenous hunting culture threatened by retreating sea ice and changing environment • Health impacts via stresses on food security and safety of travel conditions • Emergence of zoonotic diseases as a threat to human health • Increased outdoor leisure and recreational opportunity, plus lower heating costs

Table 18.9 summarizes the key consequences of climate change on the environment, the economy, and people's lives in each of the four regions. The following sections provide additional information by region. Projections of climate change for each region are based on output from the five ACIA-designated climate models.

18.3.1. Region 1

18.3.1.1. Changes in climate

Most of Region 1 experienced a modest increase in mean annual temperature (about 1 ºC) between 1954 and 2003, with slightly higher winter temperature increases over this period, except for Iceland, the Faroe Islands, and southern Greenland, where there has been some cooling (see Fig. 18.2 for regional details). From 1990 to 2000, greater warming was observed in northern Scandinavia, including Iceland, Svalbard, and East Greenland, but cooling was observed in other areas such as the Kola Peninsula.

Model projections (see Fig. 18.5 for regional details) indicate that this region is likely to experience additional increases in mean annual temperature of 2 to 3 ºC in Scandinavia and East Greenland and up to 3 to 5 ºC in northwestern Russia by the late 21st century. Although changes in atmospheric and oceanic circula-

tion contributed to some cooling of the region during the 20th century, warming has occurred in recent decades and is projected to dominate throughout the 21st century. Precipitation has increased slightly and is projected to increase further by up to about 10% by the end of the century.

18.3.1.2. Impacts on the environment

The geography and environment of Region 1 are dominated by the North Atlantic Ocean, which has extensive connections with the Arctic Ocean via the Norwegian, Greenland, and Barents Seas. The North Atlantic Ocean separates Greenland in the west from the Fennoscandian, European, and western Russian landmasses in the east. Relatively isolated islands of Iceland, the Faroe Islands, and the Svalbard and Franz Josef archipelagos span the low to high arctic latitudes. The land areas are characterized by a north–south climatic contrast between low-arctic environments in the south isolated by ocean from the high-arctic environments of the high-latitude islands, and by an east–west climatic contrast between the Scandinavian landmass, which is uncharacteristically warm for its latitude, and East Greenland in the west of the region, which is heavily glaciated. The continuous south–north land corridors for movement of terrestrial and freshwater species and people found in Region 2, for example, are missing.

The Greenland, Iceland, Norwegian, and Barents Seas constitute a major part of this region. This vast oceanic area is influenced by the inflow of relatively warm Atlantic water, which enters along the coast of Norway and is the most northward branch of the Gulf Stream. Variability in the volume of this inflow, as experienced in the past and as projected by models for the future due to global climate change, is expected to have major consequences for the physical and biological regimes of the region. Sea surface temperature is expected to increase, and the Barents Sea is expected to be totally ice free in summer by 2080. Changes in the distribution of important fish stocks are expected to occur. Past integrative impact assessments of climate change in this region include publications by Lange et al. (1999, 2003) for the Barents Sea.

The arctic seas in Region 1 are projected to experience a temperature increase that will lead to a decrease in sea-ice cover, especially in summer, as well as earlier ice melt and later freeze-up. Unless compensated for by an increase in low-level cloudiness, decreases in sea-ice cover would reduce the overall planetary albedo of the region and provide a positive feedback to the global climate. The reduction in sea ice is likely to enhance primary productivity, lead to increases in zooplankton production, and possibly to increased fisheries production. Such changes would also lead to decreased natural habitat for polar bears (*Ursus maritimus*) and ringed seals (*Phoca hispida*) to an extent that is likely to threaten the survival of their populations in this region. Conversely, more open water is expected to favor some whale and seabird species.

Biodiversity is high in Region 1: around 6000 marine and terrestrial species have been recorded for Svalbard (Prestrud et al., 2004) and around 7200 species have been recorded for 22 705 km² between 68° and 70° N in northern Finland (Callaghan et al., 2004). The European Arctic and subarctic are important breeding areas for many bird species overwintering in more temperate regions. Excluding the Russian Arctic, over 43% of the European bird species pool occurs in Region 1.

Observations indicate very variable climate trends and ecological responses to them in Region 1 (see Chapter 7). Treelines in northern Sweden increased in altitude by up to 40 m during the first part of the 20th century, and a further 20 m during the warming of the past 40 years, giving recent rates of treeline increase of 0.5 m/yr and 40 m/°C (Callaghan et al., 2004). In northern Finland, the pine treeline is increasing in altitude and density, and in the Polar Ural Mountains, treeline has advanced. However, there is little evidence of a northward shift of the latitudinal treeline west of the Polar Ural Mountains. Unexpectedly, evidence shows a southward movement of the treeline in parts of the forest tundra of the Russian European Arctic, a change that appears to be associated with localized pollution, deforestation, agriculture, and the growth of bogs leading to tree death. In the Faroe Islands, there has been a lowering of the alpine altitudinal treeline in response to a cooling of 0.25 °C during the past 50 years. In some areas of Finland and northern Sweden, there is evidence of an increase in rapidly changing warm and cold episodes in winter that lead to increasing bud damage in birch. Recent warming in northern Sweden and Finland has led to a reduction in the extent of discontinuous permafrost in mires and a change in vegetation resulting in increased CH_4 flux to the atmosphere (Christensen et al., 2004).

Recent warm winters have resulted in unusual conditions (causing ice layers in the snow) unfavorable for reindeer and wildlife, and leading to an absence of lemming population peaks, and on Svalbard, a decline in wild reindeer (*Rangifer tarandus platyrhynchus*) through decreases in the availability of food resources. Changes in animal populations also include reductions in arctic fox (*Alopex lagopus*) and snowy owl (*Nyctea scandiaca*) (as well as several other bird species) populations on mainland Fennoscandia but a northward migration of larger butterflies and moths, the larvae of some being defoliators of trees and shrubs. Moose (*Alces alces*), red fox (*Vulpes vulpes*), and the invasive species mink (*Mustela vison*) are increasing in the east of the region and muskoxen (*Ovibos moschatus*), wolves, and pink-footed (*Anser brachyrhynchus*) and barnacle geese (*Branta leucopsis*) are increasing in northeast Greenland (Callaghan et al., 2004).

If warming occurs as projected, the deciduous mountain birch forest that forms much of the present treeline in the region, the boreal conifer forest and woodland, and the arctic and alpine tundra are very likely to begin shifting northward and upward in altitude. The potential for

vegetation change within the region is perhaps greatest in northern Scandinavia, where large shifts occurred in the early Holocene in response to warming. Here, pine forest is projected to invade the lower belt of mountain birch forest. The birch treeline is projected to move upward and northward, displacing shrub tundra vegetation, which in turn is projected to displace alpine tundra. Alpine species in the north are expected to be the most threatened because there is no suitable geographic area for them to shift toward in order to avoid being lost from the Fennoscandian mainland. In Iceland, a warmer climate is likely to facilitate natural regeneration of the heavily degraded native birch woodland as well as aid current and future afforestation efforts (Chapter 14). Model projections suggest that arctic tundra will be displaced totally from the mainland by the end of the 21st century (Fig. 18.1), although in practice, the bogs of the western Russian European Arctic may prevent forests from reaching the coast. Model projections of change from tundra to taiga between 1960 and 2080 (5.0%), and of change from polar desert to tundra (4.2%), are the lowest of any of the four ACIA regions because of the lack of tundra areas and the separation of the high Arctic from the subarctic.

While the climate is changing, local forest damage is projected to occur as a result of winters that are warmer than normal. Warmer winters are likely to lead to an increase in insect damage to forests and decreases in populations of animals such as lemmings and voles that depend upon particular snow conditions for survival. These changes, in turn, are likely to cause decreases in populations of many existing bird species and other animals, with the most severe effects on carnivores, such as Arctic foxes, and raptors, such as snowy owls. Heathland and wetland areas are likely to be partially invaded by grasses, shrubs, and trees, and mosses and lichens are expected to decrease in extent. Unlike other arctic areas, fire is not likely to play a major role in controlling vegetation dynamics. Any changes in land-use patterns, including increased agriculture and domestic stock production in a warmer climate, will encroach on wildlife habitats and further threaten large carnivores.

Some areas in this region, such as East Greenland and the Faroe Islands, have experienced recent cooling, and future warming is expected to reverse the present downward vegetation shifts in the mountains of the Faroe Islands. The island settings in this region, particularly those of Greenland, Svalbard, Franz Josef Land, and Novaya Zemlya, are likely to delay the arrival of immigrant species and substantial change other than expansion and increased growth of some current species.

Changes in arctic ecosystems will not only have local consequences but will also have impacts at a global level because of the many linkages between the Arctic and other regions further south. For example, several hundreds of millions of birds migrate to the Arctic each year and their success in the Arctic determines their populations at lower latitudes. As previously noted,

excluding the Russian Arctic, over 43% of the European bird species pool is found in Region 1. Changes in their wintering areas far south of the Arctic also play an important part in the ecology of migratory birds and there are many important stop-over sites and over-wintering grounds in Europe. Birds that are already suffering major declines in the region include lesser white-fronted goose (*Anser erythropus*) and shore lark (*Eremophila alpestris*) that have almost become extinct in Fennoscandia, and snowy owls. In contrast, some southern bird species have become established. Examples include blue tit (*Parus caeruleus*) and green-finch (*Carduelis chloris*) (Callaghan et al., 2004).

Changes in carbon storage and release from ecosystems also have potential global consequences. Christensen et al. (2004) estimated that CH_4 emissions have increased from between 1.8 and 2.2 mg CH_4/m^2/hr to between 2.7 and 3.0 mg CH_4/m^2/hr over the past 30 years in northern Sweden, as a result of permafrost thaw and vegetation change. Terrestrial carbon storage and net primary production are projected to increase, and albedo to decrease, but less than in any other region due to the ocean barriers and general lack of tundra: there is a transition from subarctic to high Arctic separated by seas where the mid-arctic tundra should be.

18.3.1.3. Impacts on the economy

Region 1 has abundant renewable and non-renewable resources (timber, fish, ore, oil, and natural gas). The highly productive marine life makes this region one of the most productive fishing grounds in the circumpolar North. Higher ocean temperatures are likely to cause shifts in the distribution of some fish species, as well as changes in the timing of their migration, possible extension of their feeding areas, and increased growth rates. The occurrence of several "warm years" or "cold years" in a row, which is a sequence that could occur more frequently as a result of continuing global climate change, seems likely to lead to repercussions on the major fish stocks and, ultimately, the lucrative and productive fisheries in the region. Provided that the fluctuations in Atlantic inflow to the area are maintained, along with a general warming of the North Atlantic waters, it is likely that annual recruitment in herring (*Clupea harengus*) and Atlantic cod (*Gadus morhua*) will increase from current levels and will be about the same as the long-term average during the first two to three decades of the 21st century. This projection is also based on the assumption that harvest rates are kept at levels that maintain spawning stocks well above the level at which recruitment is impaired.

Impacts of climate change on the fisheries sector of the region's economy are difficult to assess, however. A scenario of moderate warming could result in quite large positive changes in the catch of many species. A self-sustaining cod stock could be established in West Greenland waters through larval drift from Iceland. Past catches suggest that this could yield annual catches of

about 300 000 t. Should that happen, it is estimated that catches of northern shrimp (*Pandalus borealis*) will decrease to around 30% of the present level, while those of snow crab and Greenland halibut (*Reinhardtius hippoglossoides*) might remain the same. Such a shift could approximately double the export earnings of the Greenlandic fishing industry, which roughly translates into the same amount as that presently paid by Denmark to subsidize the Greenland economy. Such dramatic changes are not expected in the Icelandic marine ecosystem. Nevertheless, there would be an overall gain through larger catches of demersal species such as cod, pelagic species like herring, and new fisheries of more southern species like mackerel (*Scomber scombrus*). On the other hand capelin (*Mallotus villosus*) catches would dwindle, both through diminished stock size and the necessity of conserving this very important forage fish for other species. Effective fisheries management will continue to play a key role both for Greenland and Iceland, however. Little can be said about possible changes under substantial climate warming because such a situation is outside any recorded experience.

Forestry and agriculture are important in Region 1; both have been affected by climate change in the past and impacts are likely to occur in the future. Longer growing seasons are likely to improve the growth of agricultural crops. While growth (net carbon assimilation) of forests and woodlands is likely to increase, this will not necessarily benefit the forestry industry as forest fires and pests will also increase. Forest pest outbreaks have been reported for the Russian part of the region, including the most extensive damage from the European pine sawfly (*Neodiprion sertifer*), which affected a number of areas, each covering more than 5000 ha. The annual number of insect outbreaks reported between 1989 and 1998 was 3.5 times higher than between 1956 and 1965. The mean annual intensity of forest damage increased two-fold between 1989 and 1998. Factors other than climate change are also important to forest-based economies. For example, while most of the region has seen modest growth in forestry, Russia has experienced a decline due to political and economic factors. These socio-economic problems are expected to be aggravated by global climate change, which in the short term will have negative effects on timber quality owing to fire and insect damage and on infrastructure and winter transport when permafrost thaws.

18.3.1.4. Impacts on people's lives

The prospects and opportunities of gaining access to important natural resources, both renewable and non-renewable, have attracted a large number of people to Region 1. The relatively intense industrial activities, particularly on the Kola Peninsula, have resulted in population densities that are the highest throughout the circumpolar North. Impacts of climate change on terrestrial and marine ecosystems and implications for the availability of natural resources may lead to major

changes in economic conditions and subsequent shifts in demography, societal structure, and cultural values.

Because they would affect food, fuel, and culture, changes in arctic ecosystems and their biota are particularly important to the peoples of the Arctic. Reindeer herding by the Saami and other indigenous peoples is an important economic and cultural activity and the people who herd reindeer are concerned about the impacts of climate change. Observations have shown that during autumn the weather in recent years has fluctuated between raining and freezing so that the ground surface has often been covered with an ice layer and reindeer in many areas have been unable to access the underlying lichen. These conditions are quite different from those in earlier years and have caused massive losses of reindeer in some years. Changes in snow conditions also pose problems. Since reindeer herding has become motorized, herders relying on snowmobiles have had to wait for the first snows to start herding. In some years, this has led to delays up to the middle of November. Also, the terrain has often been too difficult to travel over when the snow cover is light. Future changes in snow extent and condition have the potential to lead to major adverse consequences for reindeer herding and those aspects of health (physical, social, and mental) relating to the livelihood of reindeer herders.

The beneficial effects of a warmer climate on people's recreational and leisure activities (camping, hiking, and other outdoor activities) should not be overlooked. Even relatively modest warming will improve people's mental and physical health. A warmer climate is also likely to reduce heating costs.

18.3.2. Region 2

18.3.2.1. Changes in climate

Region 2, which experiences the coldest conditions in the Arctic, has experienced an increase in mean annual temperature of about 1 to 3 °C since 1954, and an increase of up to 3 to 5 °C in winter (see Fig. 18.2 for regional details).

Models project that the mean annual temperature of Region 2 is likely to increase by a further 3 to 5 °C by the late 21st century, and by up to 5 to 7 °C in winter (see Fig. 18.5 for regional details). In the far north, winter warming of up to 9 °C over the Arctic Ocean as a result of reduced sea-ice extent and thickness is projected. The summer warming over the land areas is projected to be 2 to 4 °C by the end of the century, but there is likely to be very little change in summer over the Arctic Ocean.

18.3.2.2. Impacts on the environment

This region has the largest continuous land mass, which stretches from the tropical regions to the high Arctic. It is very likely to experience major changes as the

boreal forest expands northward, but tundra will persist, although with reduced area. For example, extensive tundra is likely to remain in the Taymir region but is likely to be displaced completely from the mainland in the Sakha region.

The large Siberian rivers draining into the Arctic Ocean are projected to experience major impacts. Projected increases in winter precipitation, and more importantly in precipitation minus evaporation, imply an increase in water availability for soil infiltration and runoff. The total projected increase in freshwater supplied to the Arctic Ocean could approach 15% by the latter decades of the 21st century. An increase in the supply of freshwater has potentially important implications for the stratification of the Arctic Ocean, for its sea-ice regime, and for its freshwater export to the North Atlantic. In addition, increased freshwater input into the coastal zone is likely to accelerate the degradation of coastal permafrost.

On land, the projected increase in precipitation is likely to lead to wetter soils when soils are not frozen, wetter active layers in summer, and greater ice content in the upper soil layer during winter. To the extent that the increase in precipitation occurs as an increase in snowfall during the cold season, snow depth and snow water equivalent will increase, although the seasonal duration of snow cover may be shorter if, as projected, warming accompanies the increased snowfall.

The projected changes in terrestrial watersheds will increase moisture availability in the upper soil layers in some areas, favoring plant growth in areas that are presently moisture-limited. The projected increase in river discharge during winter and spring is likely to result in enhanced fluxes of nutrients and sediments to the Arctic Ocean, with corresponding impacts on coastal marine ecosystems. Higher rates of river and stream flow are likely to have especially large impacts on riparian regions and flood plains in the Arctic. One important consequence is that the vast wetland and bog ecosystems of this region are very likely to expand, leading to higher CH_4 emissions.

18.3.2.3. Impacts on the economy

A potentially major impact on the economy of Region 2 and on the global economy could be the opening of the Northern Sea Route (Northeast Passage) to commercial shipping. Model projections of ice cover during the 21st century show considerable development of ice-free areas around the entire Arctic Basin. Most coastal waters of the Eurasian Arctic are projected to become relatively ice free during September by 2020, with more extensive melting occurring later in the century. Ships navigating the Northern Sea Route would clearly benefit from these ice-free conditions. In addition, if winter multi-year sea ice in the central Arctic Ocean continues to retreat, it is very likely that first-year sea ice will dominate the entire maritime Eurasian Arctic, with a decreasing frequency of multi-year ice intrusions into the coastal seas and more

open water during the summer. By 2100, one of the ACIA-designated models projects that the navigation season could be as long as 200 days, while the mean of the five ACIA-designated models projects a navigation-season length of 120 days (when defined as the period with sea-ice concentrations below 50%).

Such changes in sea-ice conditions are likely to have important implications for ship design and construction and route selection along the Northern Sea Route in summer and even in winter. The need for navigational aids, refueling and ship maintenance, and sea-ice monitoring will require major financial investment, however, to assure security and safety for shipping and protection of the marine environment.

The coal and mineral extraction industries in Region 2 are important parts of the Russian economy, but climate change is likely to have little effect on the actual extraction process. On the other hand, transportation of coal and minerals will be affected in both a positive and negative sense. Mines in Siberia that export their products by ship will experience savings resulting from reduced sea-ice extent and a longer shipping season. However, mining facilities relying on transport over roads on permafrost will experience higher maintenance costs as the permafrost thaws.

Forestry, another important sector of the Siberian economy, is likely to experience both positive and negative impacts. A potentially longer growing season and warmer climate are likely to enhance productivity. However, more frequent fires and insect outbreaks are likely as the climate warms and insects invade from warmer regions. Drying of soils as permafrost thaws is also likely to affect forest productivity in some areas. To meet the demands of the global economy, forestry is likely to become more important and transportation of wood and wood products to markets will improve as reduced sea-ice extent facilitates marine transport along the Siberian coast.

18.3.2.4. Impacts on people's lives

The change to a wetter climate is likely to lead to increased water resources for the region's residents. In permafrost-free areas, water tables are very likely to be closer to the surface, and more moisture is projected to be available for agricultural production. During the spring when enhanced precipitation and runoff are very likely to cause higher river levels, the risk of flooding will increase. Summer soil moisture changes remain an open question since the models do not give clear signals. It is possible that lower water levels will occur in summer, as projected for other regions (for example the Mackenzie River in Region 3), affecting river navigation in some areas, increasing the risk of forest fires, and affecting hydropower generation.

Other major environmental impacts projected for Region 2 are associated with thawing permafrost and

melting sea ice. Warming during the 20th century produced noticeable impacts on permafrost, causing deeper seasonal thawing and changes in the distribution and temperature of the frozen ground. For example, from the late 1980s to 1998, temperatures in the upper permafrost layers increased by 0.1 to 1.0 °C on the western Yamal Peninsula. Permafrost degradation in the developed regions of northeast Russia, coupled with inadequate building design, has led to serious problems. For example, in 1966 a building affected by thermokarst and differential thaw settlement collapsed in Norilsk, killing 20 people. In Yakutsk, a city built over permafrost in central Siberia, more than 300 structures, including several large residential buildings, a local power station, and a runway at the airport, have been seriously damaged by thaw-induced settlement. Considerable advances in knowledge and technology for building on permafrost have been made in recent decades. Nevertheless, as global climate change continues to intensify changes in arctic climate, detrimental impacts on infrastructure and therefore on the economy, health, and well-being of the population throughout the permafrost regions are expected to increase.

18.3.3. Region 3

18.3.3.1. Changes in climate

Alaska experienced an increase in mean annual temperature of about 2 to 3 °C between 1954 and 2003. The temperature increase was similar in the western Canadian Arctic, but was only about 0.5 °C in the Bering Sea and Chukotka. Winter temperatures over the same period increased by up to 3 to 4 °C in Alaska and the western Canadian Arctic, but Chukotka experienced winter cooling of between 1 and 2 °C (see Fig. 18.2 for regional details).

The five ACIA-designated models project that mean annual temperatures will increase by 3 to 4 °C by the late 21st century (see Fig. 18.5 for regional details). All the models project that the warming is likely to be greater in the north, reaching up to 7 °C in winter. In the central Arctic Ocean, winter temperatures are projected to increase by up to 9 °C as a result of reduced sea-ice extent and thickness, but there is likely to be very little change in summer temperature. Trends in and future projections of ozone and UV radiation levels follow the Arctic-wide patterns.

18.3.3.2. Impacts on the environment

Two detailed assessments of the potential consequences of climate variability and change have been conducted in Region 3: one for the Mackenzie River watershed in Canada (Cohen, 1997a,b) and the other for Alaska and the Bering Sea (NAST, 2000, 2001; Weller et al., 1999) as part of the US Global Change Research Program. The Canada Country Study (Environment Canada, 1997) described impacts in the Yukon Territory. These assessments provided background information and input

for this assessment. No detailed impact studies have been conducted for Chukotka.

The entire region, but particularly Alaska and the western Canadian Arctic, has undergone a marked change over the last three decades, including a sharp reduction in snow-cover extent and duration, shorter river- and lake-ice seasons, melting of mountain glaciers, sea-ice retreat and thinning, permafrost retreat, and increased active-layer depth. These changes have caused major ecological and socio-economic impacts, which are likely to continue or worsen under projected future climate change. Thawing permafrost and northward movement of the permafrost boundary are likely to increase slope instabilities, which will lead to costly road replacement and increased maintenance costs for pipelines and other infrastructure. The projected shift in climate is likely to convert some forested areas into bogs when ice-rich permafrost thaws. Other areas of Alaska, such as the North Slope, are expected to continue drying. Reduced sea-ice extent and thickness, rising sea level, and increases in the length of the open-water season in the region will increase the frequency and intensity of storm surges and wave development, which in turn will increase coastal erosion and flooding.

Warmer temperatures have resulted in some northward expansion of boreal forest, as well as significant increases in fire frequency and intensity, unprecedented insect outbreaks, and a 20% increase in growing-degree days. The latter has benefited both agriculture and forestry. The expansion of forests in most areas and their increased vulnerability to fire and pest disruption are projected to increase. One simulation projects a three-fold increase in the total area burned per decade, destroying coniferous forests and eventually leading to a deciduous forest-dominated landscape on the Seward Peninsula in Alaska, after a warmer climate has led to forestation of the present tundra areas. Shrubbiness is already increasing in this area, a trend that is likely to continue.

Observations in the Bering Sea have shown abnormal conditions during recent years. The changes observed include significant reductions of seabird and marine mammal populations, unusual algal blooms, abnormally warm water temperatures, and low harvests of salmon on their return to spawning areas. Some of the changes observed in the 1997 and 1998 summers, such as warmer ocean temperatures and altered currents and atmospheric conditions, may have been exacerbated by the very strong El Niño event, but the area has been undergoing change for several decades. While the Bering Sea fishery has become one of the world's largest, the abundance of Steller sea lions (*Eumetopias jubatus*) has declined by between 50 and 80%. Northern fur seal (*Callorhinus ursinus*) pups on the Pribilof Islands – the major Bering Sea breeding grounds – declined by 50% between the 1950s and the 1980s. There have been significant declines in the populations of some seabird species, including common murre (*Uria aalge*), thick-billed murre (*U. lomvia*), and red- and blacklegged kitti-

wakes (*Rissa brevirostris* and *R. tridactyla*, respectively). Also, the number of salmon has been far below expected levels, the fish were smaller than average, and their traditional migratory patterns seemed to have altered.

Differentiating between the various factors affecting the Bering Sea ecosystem is a major focus of current and projected research. Well-documented climatic regime shifts occurred in the Bering Sea during the 20th century on roughly decadal time scales, alternating between warm and cool periods. A climatic regime shift occurred in the Bering Sea in 1976, changing the marine environment from a cool to a warm state. Information from the contrast between the warm and subsequent cool period forms the basis of projected responses of the Bering Sea ecosystem to scenarios of future warming. These projections show increased primary and secondary productivity with greater carrying capacity, poleward shifts in the distribution of some cold-water species, and possible negative effects in ice-associated species.

18.3.3.3. Impacts on the economy

Large oil and gas reserves exist in Alaska along the Beaufort Sea coast and in the Mackenzie River/Beaufort Sea area of Canada. To date, climate change impacts on oil and gas development in Region 3 have been minor but are likely to result in both financial costs and benefits in future. For example, offshore oil exploration and production is likely to benefit from less extensive and thinner sea ice, allowing savings in the construction of platforms that must withstand ice forces. Conversely, ice roads, now used widely for access to offshore activities and facilities, are likely to be less safe and useable for shorter periods; the same applies for over-snow transport on land given projected reductions in snow depth and duration. The thawing of permafrost, on which buildings, pipelines, airfields, and coastal installations supporting oil development are located, is very likely to adversely affect these structures and greatly increase the cost of maintaining or replacing them.

It is difficult to project impacts on the lucrative Bering Sea fisheries because many factors other than climate are involved, including fisheries policies, market demands and prices, harvesting practices, and fisheries technology. Large northward changes in the distribution of fish and shellfish are likely with a warmer climate. Relocating the fisheries infrastructure (fishing vessels, home ports, processing plants) may be necessary, and would incur substantial costs. Warmer waters are likely to lead to increased primary production in some regions, but a decline in cold-water species such as salmon and pollock.

Other economic sectors in this region, including forestry and agriculture, are far less developed and currently less important than oil and gas and fish and wildlife. Owing to this, economic impacts on forestry and agriculture resulting from climate change are unlikely to be significant, except locally. Impacts on tourism,

which is a large economic sector in this and other regions, are more difficult to assess, largely due to the relationship between tourism and economic conditions and social factors outside the Arctic. It is also unclear which features of Region 3 are primarily responsible for attracting tourists – large, undeveloped landscapes will not be directly affected by climate change, whereas marine mammal populations and accessible glaciers are likely to experience major changes. Whether such changes will reduce tourist interest is difficult to assess without more information.

18.3.3.4. Impacts on people's lives

Traditional lifestyles are already being threatened by multiple climate-related factors, including reduced or displaced populations of marine mammals, seabirds, and other wildlife, and reductions in the extent and thickness of sea ice, making hunting more difficult and dangerous. Indigenous communities depend on fish, marine mammals, and other wildlife, through hunting, trapping, fishing, and caribou/reindeer herding. These activities play social and cultural roles that may be far greater than their contribution to monetary incomes. Also, these foods from the land and sea make significant contributions to the daily diet and nutritional status of many indigenous populations and represent important opportunities for physical activity among populations that are increasingly sedentary.

Climate change is likely to have significant impacts on the availability of key marine and terrestrial species as food resources. At a minimum, salmon, herring, char, cod, walrus, seals, whales, caribou, moose, and various species of seabird are likely to undergo shifts in range and abundance. This will entail major local adjustments in harvest strategies and allocations of labor and equipment.

The following impacts on the lifestyles in indigenous villages and communities in Alaska and Canada, which depend heavily on fishing and hunting, have been observed in recent years:

- access to tundra and offshore food resources has been impeded by higher temperatures with milder winters, shorter duration of snow cover and sea ice, and less (or no) shore-fast ice and snow;
- recent decreases in anadromous fish stocks, which make up 60% of wildlife resources harvested by local residents, have directly affected their dietary and economic well-being;
- availability of marine mammals for local harvests has declined in some areas due to population declines associated with shifts in oceanographic and sea-ice conditions. Marine mammals are an important food source in many coastal communities;
- sea-level rise, permafrost thawing, and storm surges have triggered increased coastal erosion and threatened several villages along the Bering and Beaufort Sea coasts. The only long-term option

available has been to plan for relocation of villages, which will be very costly;

- storm surges have also reduced the protection of coastal habitats provided by barrier islands and spits, which are highly vulnerable to erosion and wave destruction; and
- infrastructure in villages constructed in or over permafrost has been affected by thawing permafrost and storm surges breaching coastlines into water supplies and sewage lagoons.

Changes in diet, nutritional health, and exposure to air-, water-, and food-borne contaminants are also likely. Adjustments in the balance between the "two economies" of rural areas (traditional and wage) will be accelerated by climate change. This suite of changes will be complex and largely indirect because of the mediating influences of market trends, the regulatory environment, and the pace and direction of rural development.

Other impacts are likely to occur in the future and have a substantial impact on people. For example:

- a decrease in the area of pack ice is projected to have important implications for primary productivity and the entire food chain. For example, walrus (*Odobenus rosmarus*) and bearded seals (*Erignathus barbatus*) require sea ice strong enough to support their weight, and ringed seals require stable shore-fast ice with adequate snow cover. Diving from ice over shallow waters allows walrus to reach the bottom to feed, and reductions in the extent and thickness of sea ice will adversely affect this species;
- as the boreal forest and associated shrub communities expand northward at the expense of tundra, changes in habitats, migration routes, ranges, and distribution and density of a number of wildlife species, particularly caribou and moose, are projected;
- a change in vegetation and landscape, affecting wildlife, is likely to change hunting practices, location of settlements, and local economic opportunities for people in many arctic regions;
- among wildlife species used as food, existing zoonotic diseases such as brucellosis and echinoccus are likely to become a greater threat to humans and wildlife. New diseases, such as West Nile virus, are likely to become established in a progressively warmer climate;
- lower water levels in some river basins, for example the Mackenzie River, cause increased erosion of riverbanks due to thawing permafrost. This erosion is very likely to increase the incidence of landslides, which have the potential to adversely affect community infrastructure; and
- more vigorous atmospheric and oceanic circulations are likely to increase the transport of contaminants from agricultural activities as well as military and industrial installations to arctic communities, both directly and via the food chain.

18.3.4. Region 4

A major integrative impact assessment for the region was published by Maxwell (1997) for the Canadian Arctic (encompassing the regions of the Northwest Territories and Nunavut). The Mackenzie River watershed assessment, mentioned in the summary for Region 3, also covers Region 4 (Cohen, 1997a,b). A number of studies of the traditional ecological knowledge of indigenous peoples of Region 4 have been conducted and are cited in earlier chapters. Detailed studies of integrated climate impacts in Greenland, on the other hand, have not been conducted prior to the ACIA.

18.3.4.1. Changes in climate

Temperature changes over the past decades have varied across Region 4. The amount of change depends on the time period chosen and, as shown in Chapter 2, the warming has been pronounced since 1966. Between 1954 and 2003, mean annual temperatures across most of arctic Canada increased by as much as 2 to 3 ºC (see Fig. 18.2a), while temperatures in northeastern Canada, including Labrador and adjacent waters, showed little change. The southern part of West Greenland (including the surrounding ocean) cooled by about 1 ºC while northern Greenland warmed by 1 to 2 ºC. Winter temperature trends over the same period were noticeably warmer in the west and colder in the east than the annual trends (Fig. 18.2b). The landmass to the west of Hudson Bay warmed by up to 4 ºC in winter while the area around Labrador, Baffin Island, and southwest Greenland experienced winter cooling of more than 1 ºC.

Annual precipitation in Region 4 has increased over the past 50 years or so, and while seasonal differences were evident around the middle of the century, increases in precipitation have been evident in all seasons over the past few decades.

The physical complexity of the Queen Elizabeth Islands and the orography of Greenland create particular challenges for modeling past, present, and future arctic climate. Models project warming throughout Region 4 during the 21st century, with no cooling projected in any season. Figures 18.5a and 18.5b illustrate annual and winter temperature changes for the period 2071–2090 relative to the 1981–2000 baseline, projected by the five ACIA-designated models forced with the B2 emissions scenario. Projected winter warming in the Canadian areas of Region 4 ranges from about 3 ºC up to about 9 ºC, with the greatest warming projected to occur around southern Baffin Island and Hudson Bay, and substantially less warming projected in other seasons. Greenland is also projected to warm but the warming is weaker (up to about 3 ºC by 2071–2090) and more consistent across seasons.

Precipitation increases are projected to be greatest in autumn and winter, and the areas of greatest increase (up to 30% by the end of the 21st century) generally

correspond with the areas of greatest warming. Almost all areas of Region 4 are projected to experience some increase in precipitation after the first few decades of the 21st century.

18.3.4.2. Impacts on the environment

The Canadian part of Region 4 has significant areas of warm permafrost that are at risk of thawing with rising regional air temperatures. The boundary between continuous and discontinuous permafrost is projected to shift poleward, following, but with a lag in timing, the several-hundred-kilometer movement of the isotherms of mean annual temperature over the 21st century. This is likely to result in the disappearance of a substantial amount of the permafrost in the present discontinuous zone. Areas of warm permafrost are also likely to experience more widespread thermokarst development where soils are ice-rich, and increases in slope instability. In areas of remaining continuous and cold permafrost, increases in active-layer depth can be expected.

The maximum northward retreat of sea ice during summer is projected to increase from its present range of 150–200 km to 500–800 km. The thickness of fast ice in the Northwest Passage is likely to decrease substantially from its current value of 1 to 2 m.

The Greenland Ice Sheet is presently losing mass in its ablation zone and is likely to contribute substantially to sea-level rise in the future. While precipitation is projected to increase, it is possible that increased evaporation rates will lead to lower river and lake levels during the warm season.

In general terms, and consistent with results for other regions, the biomes of arctic Canada and Greenland are expected to change. Reductions in the area covered by polar deserts in Canada and Greenland are likely to result from the northward shift of the tundra, while reductions in the areas covered by arctic tundra are very likely to result from the northward shift of the treeline. Polar deserts in the region are extensive, and these areas could sequester large amounts of carbon dioxide (CO_2) if tundra vegetation displaces polar deserts. A reduction in polar desert area of about 36% by 2080 is projected, leading to the greatest projected carbon gain of any region. In contrast, increases in temperature and precipitation are likely to lead to relatively small increases in the area of taiga compared with other regions.

Many treelines, such as those in northeast Canada, have been relatively stable for the last few thousand years. A widespread and consistent observation from the late 20th century has been the infilling of sparse stands of trees near the tundra edge into dense stands that no longer retain the features of the tundra. Movement of the treeline northward is likely when climatic conditions become favorable, but the actual movement of trees will lag the climate warming considerably in time. The forests of northwestern Canada have recently experienced forest

health problems driven by insects, fire, and tree growth stress that are all associated with recent mild winters and warmer growing seasons. These findings for Region 4 complement those of Region 3 and accord with very large-scale environmental changes in the western North America subarctic. It is very likely that such forest health problems will become increasingly intense and widespread in response to future regional warming.

The Canadian High Arctic is characterized by land fragmentation within the archipelago and by large glaciated areas, leading to constraints on species movement and establishment. In West Greenland, loss of habitat and displacement of species in combination with time delays in species immigration from the south will ultimately lead to loss of the present biodiversity. However, Region 4 contains relatively few rare and endemic vascular plant species and threatened animal and plant species, compared with the other three regions, so biodiversity losses are likely to be less significant here.

Changes in timing and abundance of forage availability, insect harassment, and parasite infestations will increase stress on caribou, tending to reduce their populations. The ability of high-arctic Peary caribou and muskoxen to forage may become increasingly limited as a result of adverse snow conditions, in which case numbers will decline, with local extirpation in some areas. Direct involvement of the users of wildlife in its management at the local level has the potential for rapid management response to changes in wildlife populations and their availability for harvest.

Arctic freshwater systems are particularly sensitive to climate change because many hydro-ecological processes respond to even small changes in climatic regimes. These processes may change in a gradual way in response to changes in climate or in an abrupt manner as environmental or ecosystem thresholds are exceeded. Pronounced potential warming of freshwater systems in the autumn is particularly important because this is typically when these systems along the coastal margins currently experience freeze-up. Such warming is projected to delay freeze-up by up to 25 days in parts of Region 4. Also, high-latitude cold-season warming is likely to lead to less severe ice breakups and flooding as the spring flood wave pushes northward along arctic rivers. Hence, future changes in the spring timing of lake- and river-ice breakup and the export of freshwater to the Arctic Ocean are likely.

With respect to freshwater ecosystems, significant shifts in species range, composition, and trophic relations are also very likely to occur in response to the projected changes. Salmonids of northern Québec and Labrador, such as native Atlantic salmon and brook trout (*Salvelinus fontinalis*) and introduced brown trout (*Salmo trutta*) and rainbow trout (*Oncorhynchus mykiss*), are likely to extend their ranges northward. Because of these range extensions, the abundance of Arctic char (*Salvelinus alpinus*) is likely to be reduced throughout much of the southern

part of Region 4, and brook trout are likely to become a more important component of native subsistence fisheries in rivers now lying within the tundra zone. Lake trout (*Salvelinus namaycush*) are also likely to disappear from rivers and the shallow margins of many northern lakes, and northern pike (*Esox lucius*) are expected to reduce in both numbers and size throughout much of their current range.

Marine mammal populations are likely to decline as the sea ice recedes but the populations of beluga and bowhead whales (*Delphinapterus leucas* and *Balaena mysticetus*, respectively) could increase (depending on the extent to which these whales become more vulnerable to predation as sea-ice cover decreases). If the Arctic Ocean becomes seasonally ice free for several years in a row, it is possible that polar bears would become extinct. Sea-level rise will change the location and distribution of coastal habitats for seabirds and some species of marine mammals (e.g., walrus haul-outs may become inundated).

18.3.4.3. Impacts on the economy

Oil and gas extraction and mining are active industries in Region 4. Diamond mining is underway in the Northwest Territories, and the development of a large nickel deposit in Voisey's Bay, Labrador, has recently been announced. Many rivers in the northern parts of Québec, Ontario, and Manitoba have been dammed for their hydroelectric potential. Roads, airstrips, and ports have been constructed and are essential to the economic infrastructure supporting these activities. Any expansion of oil and gas activities, mining, agriculture, or forestry is likely to require expansion of supporting infrastructure, including air, marine, and land transportation systems. Ice roads in nearshore areas and over-snow transport on land, systems that are important and are even now experiencing shorter seasons, are likely to be further curtailed in the future because of reduced extent and duration of sea ice and snow.

With reduced summer sea-ice extent, the shipping season in Canadian arctic waters is likely to be extended, although sea-ice conditions are likely to remain very challenging. Extension of the shipping season will result in costs and benefits, both of which are speculative. Benefits are likely to result from increased access to the natural resources of the region. As sea level rises, this will also benefit shipping by creating deeper drafts in harbors and channels. On the other hand, increased costs would result from greater wave heights, and possible flooding and erosion threats to coastal facilities. Increased rates of sediment movement during longer, more energetic open-water seasons are likely to increase rates of port and harbor infill and increase dredging costs. Increased ship traffic in the Northwest Passage will increase the risks and potential environmental damage from oil and other chemical spills.

Warmer air temperatures would be expected to reduce the power demand for heating, reduce insulation needs, and increase the length of the summer construction season. Other infrastructure likely to be affected by climate change includes northern pipeline design (negative); pile foundations in permafrost (negative but depending on depth of pile); bridges, pipeline river crossings, dikes, and erosion protection structures (negative); and open-pit mine wall stability (negative).

Impacts on marine fisheries in the eastern part of Region 4, under a moderate gradual warming, are likely to include a return to a cod–capelin system with a gradual decline in northern shrimp and snow crabs. Under more modest assumptions of ocean warming, the range of demersal species (those that tend to live near the bottom) are expected to expand northward. If ocean warming is more extreme, it is likely that the southern limit of the range of the demersal species would move northward. Many existing capelin-spawning beaches are likely to disappear as sea levels rise. If there is an increase in demersal spawning by capelin in the absence of new spawning beaches, capelin survival may decline. Seals may experience higher pup mortality as sea ice thins. Increases in regional storm intensities may also result in higher pup mortality. A reduction in the extent and duration of sea ice is likely to permit fishing further to the north and is likely to shorten the duration of Greenland halibut fisheries that are conducted through fast ice.

Impacts on freshwater and anadromous fisheries, and their economic benefits, such as tourism and local economic development, will vary across Region 4 and will depend on the local present-day and future species composition. Initially, local productivity associated with present-day freshwater and anadromous species is likely to increase, but as critical thresholds are reached (e.g., thermal limits) and as new species move in to the area, arctic-adapted species such as Arctic char are likely to experience declines in abundance and ultimately become extirpated. Loss of suitable habitat will result in decreased individual growth and declines of many populations, with resulting impacts on sport fisheries and local tourism.

18.3.4.4. Impacts on people's lives

The changes in climatic and environmental conditions projected for Region 4, and already being observed in some parts, affect people's lives in many ways. Seasonal unpredictability throughout Region 4 has already created dangerous environmental situations. For example, for the Inuit west of Hudson Bay, changing wind patterns and snow conditions make it difficult to build igloos as the snow is packed too hard. As a result, Inuit report increasing difficulty in building shelters during unexpected storms. In areas of Nunavik and Labrador the snow changes can differ, for example the type of snow now seen does not pack well enough. Changes in weather and ice conditions, such as earlier spring melt, later freeze-up, and formation of more cracks, such as those reported in the Kitikmeot region of Nunavut, result in

increasingly difficult travel conditions and sometimes shifts in regular travel and harvesting times.

The changes in local environments experienced by the people in the Canadian part of Region 4 include thinner sea ice, early breakup and later freeze-up of sea ice and lake ice, sudden changes in wind direction and intensity, earlier and faster spring melt periods, decreasing water levels in mainland lakes and rivers, and the introduction of non-native animal and bird species. These changes affect lifestyles through changes in the timing of animal migrations as well as in the numbers and health of some animal populations, and in the quality of animal skins and pelts. The distribution and quality of animals and other resources will affect the livelihoods, and ultimately the health of northern communities in Region 4. For example, a shorter winter season with increased snowfall and less extensive and thinner sea ice is likely to decrease the opportunity and increase the risks for indigenous people to hunt and trap.

Other health impacts may arise from the introduction of new or increasingly present zoonotic and/or vector-borne diseases (e.g., potential spread of West Nile virus into warmer regions in the western Arctic), changes in exposure to UV radiation and contaminants that already threaten confidence in and safety of traditional diets, and the associated social and cultural impacts of this combination of changes. Relocation of low-lying communities may be forced by rising sea levels, with serious social impacts. Where these challenges to health already exist, and where infrastructure and support systems are stretched, the effects are likely be experienced to a greater extent and at a faster pace than elsewhere.

Many changes are reported and are currently experienced by Inuit, Dene, Gwitch'in, and other indigenous peoples in Region 4. These changes represent challenges to aspects of northern indigenous cultures and lifestyles that have existed for centuries. The ability of communities to cope with and adapt to climate-driven changes is also influenced by a number of other factors and is constrained by current social and economic aspects. For example, moving people to follow shifting resources is no longer an option with permanent settlements. Other factors complicating adaptations to change include regional resource regulations, industrial development, and global economic pressures. Climate change interacts with such forces and must be considered in assessing local risks and responses. As existing adaptation strategies become obsolete, new adaptations to climate impacts must develop as northern communities adjust to the many social, institutional, and economic changes related to land claim settlements, changes in job opportunities, and the creation of new political and social structures in the North.

18.4. Cross-cutting issues in the Arctic

This assessment has dealt with individual topics that reflect traditional academic and practical organization.

However, a strong thread running through the assessment is the interaction between the various topics and processes in the Arctic. This includes, for example, the *interactions* between physical atmospheric processes and biological processes in the major ecosystems, and the strong albedo and other feedback responses; the physical and biological *connections* between land, freshwater, and marine environments; and the integrity of the arctic system as a whole. Three important cross-cutting issues that illustrate the interactions within the Arctic and connections with the global system are carbon storage and carbon cycling, biodiversity, and abrupt climate change and extreme events.

18.4.1. Carbon storage and carbon cycling

18.4.1.1. Global importance of carbon in the Arctic

The Arctic contains large stores of carbon that have historically been sequestered from the atmospheric carbon pool. Estimates of arctic and boreal soil carbon (C) in the upper meter of soil vary considerably, ranging from 90 to 290 Pg C in upland boreal forest soils, 120 to 460 Pg C in peatland soils, and 60 to 190 Pg C in arctic tundra soils. There is also a general sparsity of high-latitude carbon data for aquatic ecosystems relative to arctic terrestrial systems, but some estimates from boreal lakes indicate that reserves can be significant (120 Pg C). An additional 450 Pg of organic C is stored as dissolved carbon in the Arctic Ocean (see Chapter 9). Estimates of carbon stored in the upper 100 meters of permafrost are as high as 10 000 Pg C (Semiletov, 1999). In any case, the carbon stored in northern boreal forests, lakes, tundra, the Arctic Ocean, and permafrost is considerably greater than the *global* atmospheric pool of carbon, which is estimated at 730 Pg C (IPCC, 2001). In addition, up to 10 000 Pg C in the form of CH_4 and CO_2 is stored as hydrates in marine permafrost below 100 m (Chapter 9), however, this figure is a maximum of estimates that span several orders of magnitude.

18.4.1.2. Spatial patterns of carbon storage

Within the Arctic, carbon storage generally decreases from south to north. On land, this represents parallel decreases from boreal forest to tundra to polar desert and from southern isolated, sporadic, and discontinuous permafrost to continuous permafrost in the north; in freshwater ecosystems there is a decrease from peatlands and lakes with high concentrations of dissolved organic carbon to tundra and high-arctic ponds with low dissolved organic carbon; and in the marine environment there is a decrease from areas of high organic matter production and sedimentation in the south and at the ice margin to relatively clear waters in the Arctic Ocean. Marine permafrost and gas hydrates show a different pattern in that they are concentrated in the area of continental shelves, which are particularly extensive along the northern coastlines of the arctic landmasses.

18.4.1.3. Processes involved in carbon storage and release

Over thousands of years, an imbalance between photosynthesis and decomposition has led to storage of carbon in lake and ocean sediments, and in forest and tundra soils (Chapters 7, 8, 9, and 14). On land, this imbalance was created because low temperatures, particularly when combined with high soil moisture, retarded microbial decomposition more than photosynthesis. In the marine environment, atmospheric carbon is dissolved as inorganic carbon in surface waters and stored at depth as a result of the physical pump; death and decomposition of organisms also lead to carbon storage in the form of dissolved and particulate organic carbon (Chapter 9). Low ocean temperatures have resulted in high solubility of carbon, while extensive sea-ice cover has reduced the duration and area for carbon exchange between air and surface waters (and thus photosynthesis).

Because low temperatures have been so important for the capture and storage of atmospheric carbon in the Arctic, projected temperature increases have the potential to lead to the release of old and more recently captured carbon to the atmosphere, although the older the stored carbon, the less responsive it will be to projected climate changes. The release of stored carbon will increase atmospheric GHG concentrations and provide a positive feedback to the climate system. However, increased temperatures are also likely to increase the photosynthetic capture of atmospheric carbon if other environmental conditions do not become limiting. On land, plants will grow faster and more productive vegetation will successively replace less productive vegetation at higher latitudes and altitudes (Chapters 7 and 14). In freshwater ecosystems, reduced duration of ice cover over lakes and ponds and increased temperatures are likely to increase primary production (Chapter 8). In the marine environment, primary production is expected to increase as areas where production has been limited by sea-ice cover become more restricted in extent. Also, it is likely that more carbon will be buried as deposition shifts from the continental shelves where primary production is currently concentrated to the deeper slope and basin region as the ice edge retreats (Chapter 9).

The balance between the opposing processes of increased carbon capture and release will determine future changes in the carbon feedback from the Arctic to global climate. However, there are great uncertainties in calculating this balance across permafrost, terrestrial soil, ocean, and freshwater systems and no quantitative integrative assessment has been performed to date.

18.4.1.4. Projected changes in carbon storage and release to the atmosphere

There is a consensus from the trace-gas measurement researchers that the terrestrial Arctic is presently a source of carbon and radiative forcing, but is likely to become a weak sink of carbon during future warming

(Chapter 7). Modeling approaches suggest that circumpolar mean carbon uptake is likely to increase from the current 12 g $C/m^2/yr$ to 22 g $C/m^2/yr$ by 2100 and that carbon storage is likely to increase by 12 to 31 Pg C depending on the ACIA climate scenario used. However, the uncertainties are great: the projections are limited to terrestrial ecosystems and do not include carbon stored in permafrost and gas hydrates. Potential increases in human and natural disturbances are further uncertainties. The marine environment has been suggested as a weak sink, but the amount of carbon that the Arctic Ocean can sequester is likely to increase significantly under scenarios of decreased sea-ice cover, both through surface uptake and increased biological production, although there may be an abrupt release of CO_2 and CH_4 from thawing permafrost in marine sediments.

In the marine environment, there are vast stores of CH_4 and CO_2 (at least 10 000 Pg C in the form of gas hydrates in marine permafrost below 100 m; Semiletov, 1999). As there are currently about 4 Pg C in CH_4 in the atmosphere, even the release of a small percentage of CH_4 from gas hydrates could result in an abrupt and significant climate forcing (Chapter 9). The process of CH_4 release from gas hydrates under continental shelves could already be occurring due to the warming of earlier coastal landmasses during Holocene flooding. On land, however, natural gas hydrates are found only at depths of several hundreds of meters and are relatively inert.

18.4.2. Biodiversity

18.4.2.1. Background

The diversity of species in terrestrial, freshwater, and marine ecosystems of the Arctic is fundamental to the life support of the residents of the region and to commercial interests such as fishing at lower latitudes. Diversity is also important to the functioning of arctic ecosystems: productivity, carbon emissions, and albedo are all related to specific characteristics of current arctic species. While the Arctic contains some specialist species that are well adapted to the harsh arctic environment, it also contains species that migrate and contribute to the biodiversity of more southerly latitudes. Each year, whales, dolphins, and hundreds of millions of birds migrate from the Arctic to warmer latitudes. The Arctic is an area of relatively undisturbed and natural biodiversity because of generally lower human impacts than elsewhere on earth. However, at its southern border, human impacts are greater and particular areas, such as old growth forests on land, preserve biodiversity that is endangered in managed areas.

18.4.2.2. Patterns of diversity in the Arctic

The diversity of living organisms at any one time in the Arctic is a snapshot of complex, dynamic physical and biological processes that create habitats and opportunities or constraints for species, and genetically distinct populations of particular species, to colonize them.

The current diversity of organisms in the Arctic has been shaped by major climatic and associated changes in physical and chemical conditions of the land, wetlands, and oceans over past glacial and interglacial periods. Changes are presently occurring that are also driven by direct human activities such as fishing, hunting, and gathering, changes in land use, and habitat fragmentation, in addition to indirect human activities such as anthropogenic climate change, stratospheric ozone depletion, and transboundary movement of contaminants.

On land, and in freshwater and the marine environment, the fauna and flora are young in a geological context. Recent glaciations resulted in major losses of biodiversity, and recolonization has been slow because of the extreme environmental conditions and overall low productivity of the arctic system. On land, of at least 12 large herbivores and six large carnivores present in steppe–tundra areas at the last glacial maximum, only four and three respectively survive today and of these, only two herbivores (reindeer and musk ox) and two carnivores (brown bear, *Ursus arctos* and wolf, *Canis lupus*) presently occur in the arctic tundra biome. Arctic marine mammals to a large extent escaped the mass extinctions that affected their terrestrial counterparts at the end of the Pleistocene because of their great mobility. However, hunting in historical times had severe impacts on several species that were exterminated (great auk, *Pinguinus impennis*; Steller sea cow, *Hydrodamalis gigas*) or almost harvested to extinction (walrus; bowhead whale; sea otter, *Enhydra lutris*). Polar bears, all the Great Whales, white whales, and many species of colonially nesting birds were dramatically reduced.

The youth of arctic flora and fauna, together with the harsh physical environment of arctic habitats and to some extent over-harvesting, have resulted in lower species diversity in the Arctic compared to other regions. This results in arctic ecosystems, in a global sense, being "simple". Some of the species are specialists that are well adapted to the Arctic's physical environment; others were pre-adapted to the arctic environment and moved north during deglaciation. Overall however, many arctic species – marine, freshwater, and terrestrial – possess a suite of characteristics that allows them to survive in extreme environments. However, these characteristics, together with low diversity and simple relationships between species in food webs, render arctic species and ecosystems vulnerable to the environmental changes now occurring in the Arctic and those projected to occur in the future.

Although diversity of arctic species is relatively low, in absolute terms it can be high: about 6000 marine, freshwater, and terrestrial species have been catalogued in and around Svalbard (Prestrud et al., 2004) and about 7200 terrestrial and freshwater species have been recorded in a subarctic area of northern Finland (Callaghan et al., 2004). About 3% (around 5900 species) of the global flora occurs in the Arctic. The diversity of arctic terrestrial animals beyond the latitudinal treeline (6000 species) is nearly twice as great as that of vascular plants and bryophytes. The arctic fauna accounts for about 2% of the global total. In the arctic region as defined by CAFF (Conservation of Arctic Flora and Fauna), which includes forested areas, some 450 species of birds have been recorded breeding, and around 280 species migrate. The diversity of vertebrate species in the arctic marine environment is less than on land. Species diversity differs from group to group: primitive species of land plants such as mosses and lichens are well represented in the Arctic whereas more advanced flowering plants are not; primitive species of land animals such as springtails are well represented whereas more advanced beetles and mammals are not. In contrast, although most taxonomic groups of freshwater organisms in the Arctic are not diverse, some groups such as fish have high diversity at and below the species level. One consequence of the generally low species diversity is that species will be susceptible to damage by new insect pests, parasites, and diseases. For example, low diversity of boreal trees together with low diversity of parasites and predators that control populations of insect pests exaggerates the impacts of the pests.

The number of species generally decreases with increasing latitude. The steep temperature gradient that has such a strong influence on species diversity occurs over much shorter distances in the Arctic than in other biomes. North of the treeline in Siberia, mean July temperature decreases from 12 to 2 °C over 900 km, whereas a 10 °C decline in July temperature is spread over 2000 km in the boreal zone, and July temperature decreases by less than 10 °C from the equator to the southern boreal zone. Patterns of species diversity in the Arctic also differ according to geography. With its complicated relief, geology, and biogeographic history, there are more species on land in Beringia at a given temperature than on the Taymir Peninsula. Taymir biodiversity values are intermediate between the higher values for Chukotka and Alaska, which have a more complicated relief, geology, and floristic history, and the lower values in the eastern Canadian Arctic with its impoverished flora resulting from relatively recent glaciation. Within any region, biological hot spots occur, for example below predictable leads in the sea ice, polynyas, oceanographic fronts, areas of intense mixing, and the marginal ice zone in the marine environment; in delta areas that lie at the interface between rivers and lakes or oceans; and at the ecotone between tundra and taiga on land where elements of both forest and tundra floras and faunas mix. Such hotspots are centers from which species with restricted distributions can expand during climatic warming.

An important consequence of the general decline in numbers of species with increasing latitude is an increase in abundance and dominance. For example, on land, one species of collembolan, *Folsomia regularis*, may constitute 60% of the total collembolan density in the polar desert.

In freshwater ecosystems, midge and mosquito larvae are particularly abundant but species-level diversity is low. These "super-dominant" species, such as lemmings in peak years of their population cycles, are generally highly plastic, occupy a wide range of habitats, and generally have large effects on ecosystem processes. Similarly, arctic fish communities of the marine environment are dominated by a few species, several of which are commercially important, while the abundance of fish, marine mammals, and birds attracted hunters and fishing enterprises in historical times. Loss/reduction of one or more of these species, particularly fish species, will have disproportionate impacts on economy and ecosystem function.

18.4.2.3. Characteristics of arctic species related to the arctic environment

Several physical factors make arctic marine systems unique from other oceanic regions including: a very high proportion of continental shelves and shallow water; a dramatic seasonality and overall low level of sunlight; extremely low water temperatures (but not compared with arctic terrestrial habitats); presence of extensive permanent and seasonal sea-ice cover; and a strong freshwater influence from rivers and ice melt. Arctic freshwater environments are also characterized by extreme seasonality and low levels of incident radiation, much of which is reflected due to the high albedo of snow and ice. In addition, the thermal energy of a substantive part of this incoming radiation is used to melt ice, rendering it unavailable to biota. However, large arctic rivers with headwaters south of the Arctic act as conduits of heat and biota.

On land, low solar angles, long snow-covered winters, cold soils with permafrost, and low nutrient availability in often primitive soils limit survival and productivity of organisms. Many species of marine and terrestrial environments migrate between relatively warm wintering grounds in the south and the rich, but short-lived, feeding and breeding grounds in the Arctic. In freshwater ecosystems, some fish are highly migratory, moving in response to environmental cues. Those species that do not migrate have a suite of characteristics (behavior, physiology, reproduction, growth, development) that allow them to avoid the harshest weather or to persist. Two characteristics common to marine, freshwater, and terrestrial arctic organisms are a protracted life span with slow development over several years to compensate for the brevity and harshness of each growing/feeding/breeding season, and low reproductive rates. These characteristics render arctic organisms in general vulnerable to disturbance and environmental change.

18.4.2.4. Responses of biodiversity to climate and UV-B radiation change

The past and present patterns of biodiversity in the Arctic, the characteristics of arctic species, and the experimental and modeling assessments described in Chapters 7, 8, and 9, together make it possible to infer the following likely changes to arctic biodiversity:

- The total number of species in the Arctic will increase as new species move northward during warming. Large, northward-flowing rivers are conduits for species to move northward. New communities will form.
- Present arctic species will relocate northward, as in the past, rather than adapt to new climate envelopes, particularly as the projected rate of climate change exceeds the ability of most species to adapt. However, some species, particularly freshwater species, may already be pre-adapted to acclimate successfully to rapid climate change.
- Locally adapted species may be extirpated from certain areas while arctic specialists and particular groups of species that are poorly represented in the Arctic – some through loss of species during earlier periods of climate warming – will be at risk of extinction. Examples of arctic specialists at risk include polar bears, and seals of the ice margins in the marine environment, and large ungulates and predators on land.
- Presently super-abundant species will be restricted in range and abundance with severe impacts on commercial fisheries, indigenous hunting, and ecosystem function. Examples on land include lemmings, mosses and lichens, and some migratory birds.
- On land, shifts in major vegetation zones such as forests and tundra will be accompanied by changes in the species associated with them. For example, tree seed-eating birds, and wood-eating insects will move northward with trees.
- Low biodiversity will render ecosystems more susceptible to disturbance through insect pest infestations, parasites, pathogens, and disease.
- At the small scale, changes will be seen in the representation of different genetically separate populations within species. In cases such as Arctic char, the species may remain but become geographically or ecologically marginalized with the potential loss of particular morphs.
- Changes in UV-B radiation levels are likely to have small effects on biodiversity compared with climate warming. However, UV-B radiation has harmful effects on some fish larvae, on those amphibians that might colonize the Arctic, and on some microorganisms and fungi. In freshwater ecosystems, increased UV-B radiation levels could potentially reduce biodiversity by disadvantaging sensitive species and changing algal communities.
- All the projected changes in biodiversity resulting from changes in climate and UV-B radiation levels are likely to be modified by direct human activities. Protection and management of some areas have led to the recovery of some previously declining species while deforestation, extractive industries, and pollution have prevented forests and associated species from moving northward during

recent warming in some areas. Protection of ecosystems from the impacts of changes in climate and UV-B radiation in the long term is difficult and perhaps impossible.

18.4.3. Abrupt climate change and extreme events

Human activities are causing atmospheric concentrations of CO_2 and other GHGs and aerosols to change slowly from year to year, thereby causing the radiative forcing that drives climate change to shift slowly. However, the resulting changes in climate and associated impacts do not necessarily have to change slowly and smoothly. First, the natural interactions of the atmosphere, oceans, snow and ice, and the land surface, both within and outside the Arctic, can cause climatic conditions to fluctuate. These variations can cause months, seasons, years, and even decades to be warmer or cooler, wetter or drier, and even more settled or more changeable than the multi-decadal average conditions. Intermittent volcanic eruptions and variations or cycles in the intensity of solar radiation can also cause such fluctuations. These types of fluctuations can be larger than the annual or even decadal increment of long-term anthropogenic global climate change. Present model simulations project a slow and relatively steady change in baseline climate while natural factors create fluctuations on monthly to decadal scales. As the baseline climate changes, the ongoing fluctuations are very likely to cause new extremes to be reached and the occurrence of conditions that currently create stress (e.g., summer temperatures greater than 30 °C) are likely to increase significantly.

The climatic history of the earth shows that instead of climate changing steadily and gradually, change can be intermittent and abrupt in particular regions – even very large regions. Reconstructions of climatic variations over the last glacial cycle and the early part of the current interglacial some 8000 to 20 000 years ago suggest that temperature changes of several degrees in the large-scale, long-term climate occurred over a relatively short period. For example, ice cores indicate that temperatures over Greenland dropped by as much as 5 °C within a few years during the period of warming following the last glacial. These changes were apparently driven by a sharp change in the thermohaline circulation of the ocean (also referred to as the Atlantic meridional overturning circulation), which probably also prompted changes in the atmospheric circulation that caused large climatic changes over land areas surrounding the North Atlantic and beyond. Over multi-decadal time periods, persistent shifts in atmospheric circulation patterns, such as the North Atlantic and Arctic Oscillations, have also caused changes in the prevailing weather regimes of arctic countries, contributing, for example, to warm decades, such as the 1930s and 1940s, and cool decades, such as the 1950s and 1960s.

A recent example of a rapid change in arctic climate was the so-called regime shift in the Bering Sea in 1976,

which had serious consequences and impacts on the environment. In 1976, mean annual temperatures in Alaska experienced a step-like increase of 1.5 °C to a lasting new high level, shown as the average of several measuring stations. Sea-ice extent in the Bering Sea showed a similar step-like decrease of about 5% (Weller et al., 1999). An analysis by Ebbesmeyer et al. (1991) gave statistical measures of deviation from the normal of 40 environmental parameters in the North Pacific region, as a consequence of this rapid change. The parameters included air and water temperatures, chlorophyll, geese, salmon, crabs, glaciers, atmospheric dust, coral, CO_2, winds, ice cover, and Bering Strait transport. The authors concluded that "apparently one of the Earth's large ecosystems occasionally undergo large abrupt shifts".

As anthropogenic climate change continues, the potential exists for oceanic and atmospheric circulations to shift to new or unusual states. Whether such changes, perhaps brought on when a temperature or precipitation threshold is crossed, will occur abruptly (i.e., within a few years) or more gradually (i.e., within several decades or more) remains to be determined. Such shifts could cause the relatively rapid onset of various types of impacts. A warm and wet anomaly might accelerate the onset of pests or infectious diseases. Warming exceeding about 3 °C might initiate the long-term deterioration of the Greenland Ice Sheet as temperatures above freezing spread across the plateau in summer. The tentative indication of an initial slowing of the thermohaline circulation could change into a significant slowdown, greatly reducing the northward transport of tropical warmth that now moderates European winters. The likelihood of any such shifts or changes occurring is not yet well established, but if the future is like the past, the possibility for abrupt change and new extremes is real.

18.5. Improving future assessments

A critical self-assessment of the ACIA shows achievements as well as deficiencies. Regional impacts were only covered in an exploratory manner and are hence a priority for future assessments. The ACIA did examine climate and UV radiation impacts in the Arctic on (1) the environment, (2) economic sectors, and (3) on people's lives. Impacts on the environment were covered very extensively, but the assessment has only qualitative information on economic impacts, and this must be a priority for future assessments. Impacts on people's lives covered indigenous communities but had little information concerning other arctic residents. Integrative vulnerability studies were only covered in an exploratory manner (in Chapter 17) and need attention in the future.

Regional impacts

While the ACIA was successful in many respects, it mostly addressed impacts at the large-scale circumpolar level. An attempt to differentiate between impacts within the four ACIA regions was exploratory and did not

cover these regions in depth. There is a need to focus future assessments on smaller regions (perhaps at the landscape level) where an assessment of impacts of climate change has the greatest relevance and use for residents in the region and their activities.

Economic impacts

There are many important economic sectors in the Arctic, including oil and gas production, mining, transportation, fisheries, forestry and agriculture, and tourism. Some will gain from a warmer climate, others will not. In most cases, only qualitative information about the economic impacts (in monetary terms) of climate change is presently available. It is essential to involve a wide range of experts and stakeholders in future climate impact assessments to fill this gap and provide relevant information to users and decision makers.

Assessing vulnerabilities

Vulnerability is the degree to which a system is susceptible to or unable to cope with adverse effects of multiple and interacting stresses. Climate change occurs amidst a number of other interacting social and environmental changes across scales from local to regional and even global, and includes industrial development, contaminant transport and effects, and changes in social, political, and economic conditions. In this context it has become important to assess the vulnerabilities of coupled human–environment systems in the Arctic.

To undertake improved assessments on these three research topics a suite of improved observations and process studies, long-term monitoring, climate modeling, and impact analyses on society are necessary. These require new research efforts and studies funded by the various arctic countries.

Observations and process studies

To improve future climate impact assessments, many arctic processes require further study, both through scientific investigations and more detailed systematic documentation of indigenous knowledge. Priorities include collection of data ranging from satellite, surface, and paleo data on the climate and physical environment, to rates and ranges of change in arctic biota, and to the health status of arctic people.

Long-term monitoring

Long-term time series of climate and climate-related parameters are available from only a few locations in the Arctic. The need for continuing long-term acquisition of data is crucial, including upgrading of the climate observing system throughout the Arctic and monitoring snow and ice features, the discharge of major arctic rivers, ocean parameters, and changes in vegetation, biodiversity, and ecosystem processes.

Climate modeling

Improvements in numerical modeling of potential changes in climate are needed, including the representation in climate models of key arctic processes such as ocean processes, permafrost–soil–vegetation interactions, important feedback processes, and extreme events. The development and use of very high-resolution coupled regional models that provide useful information to local experts and decision makers is also required.

Analysis of impacts on society

Critical needs for improving projections of possible consequences for the environment and society include development and use of impact models; evaluating approaches for expressing relative levels of certainty and uncertainty; developing linkages between traditional and scientific knowledge; preparing scenarios of arctic population and economic development; and identifying and evaluating potential mitigation and adaptation measures to meet expected impacts.

18.6. Conclusions

With its almost continuous circle of land surrounding an ocean, which has a decadal circulation, the Arctic is a globally unique system and it is no accident that the Arctic Climate Impact Assessment is the first comprehensive regional assessment conducted to date. The ACIA is an authoritative synthesis of the consequences of changes in climate and UV radiation in the Arctic, involving hundreds of arctic experts. The assessment addresses the large climatic change that is very likely to occur over the 21st century and it concludes that changes in climate and in ozone and UV radiation levels are likely to affect every aspect of life in the Arctic.

However, assessment of the projected impacts of changes in climate and UV radiation is a difficult and long-term undertaking and the conclusions presented here, while as complete as present information allows, are only a first step in what must be a continuing process. There are likely to be future surprises, such as relatively rapid shifts in the prevailing trends in climatic regimes and in the frequency and intensity of extreme events; such changes, while likely, are expected to remain very difficult to project with high confidence. In future years, however, as additional data are gathered, a better understanding of the complex processes, interactions, and feedbacks will develop, and as model simulations are refined, findings and projections will be made with increasing confidence. As understanding of the climate system and its interactions with ozone amounts steadily improves, it will be possible to increase the usefulness of projections of the likely impacts in the Arctic, allowing more specificity in planning how best to adapt and respond.

An especially important task for future impact assessments will be to conduct comprehensive vulnerability studies of arctic communities, in which impacts modu-

lated by adaptive capacity are examined in the context of both environmental and societal changes. The latter include changes in resource exploitation, human population, global trade and economies, introduction of new species, contamination, and new technologies. Chapter 17 points the way in this direction. It will be important to consider the interplay between impacts due to climate change and these other drivers. It is possible that many of the adverse impacts of variability and change can be moderated or even offset by implementing strategies for coping and adaptation, for example via changes in public policy and new strategies in resource management. The perspectives and concerns of local people will also be essential to consider more fully in future vulnerability analyses. To begin to address these policy-related issues, a separate process is ongoing to discuss mitigation and adaptation, as well as research, observation, and modeling needs, and communication and education issues pertaining to the Arctic Climate Impact Assessment.

Finally, it is important to re-emphasize that climate and UV radiation changes in the Arctic are likely to affect every aspect of human life in the region and the lives of many living outside the region. While more studies and a better understanding of the expected changes are important, action must begin to be taken to address current and anticipated changes before the scale of changes and impacts further reduces the options available for prevention, mitigation, and adaptation.

Chapter 10: Principles of Conserving the Arctic's Biodiversity

Lead Author
Michael B. Usher, University of Stirling, Scotland, UK
Contributing Authors
Terry V. Callaghan, Abisko Scientific Research Station, Sweden; Sheffield Centre for Arctic Ecology, UK
Grant Gilchrist, Canadian Wildlife Service, Canada
Bill Heal, Durham University, UK
Glenn P. Juday, University of Alaska Fairbanks, USA
Harald Loeng, Institute of Marine Research, Norway
Magdalena A. K. Muir, Conservation of Arctic Flora and Fauna, Iceland; Arctic Institute of North America, Canada
Pål Prestrud, Centre for Climate Research in Oslo, Norway

Chapter 11: Management and Conservation of Wildlife in a Changing Arctic Environment

Lead Author
David R. Klein, University of Alaska Fairbanks, USA
Contributing Authors
Leonid M. Baskin, Institute of Ecology and Evolution, Russia
Lyudmila S. Bogoslovskaya, Russian Institute of Cultural and Natural Heritage, Russia
Kjell Danell, Swedish University of Agricultural Sciences, Sweden
Anne Gunn, Government of the Northwest Territory, Canada
David B. Irons, U.S. Fish and Wildlife Service, USA
Gary P. Kofinas, University of Alaska Fairbanks, USA
Kit M. Kovacs, Norwegian Polar Institute, Norway
Margarita Magomedova, Institute of Plant and Animal Ecology, Russia
Rosa H. Meehan, U.S. Fish and Wildlife Service, USA
Don E. Russell, Canadian Wildlife Service, Canada
Patrick Valkenburg, Alaska Department of Fish and Game, USA

Chapter 12: Hunting, Herding, Fishing, and Gathering: Indigenous Peoples and Renewable Resource Use in the Arctic

Lead Author
Mark Nuttall, University of Aberdeen, Scotland, UK; University of Alberta, Canada
Contributing Authors
Fikret Berkes, University of Manitoba, Canada
Bruce Forbes, University of Lapland, Finland
Gary Kofinas, University of Alaska Fairbanks, USA
Tatiana Vlassova, Russian Association of Indigenous Peoples of the North (RAIPON), Russia
George Wenzel, McGill University, Canada

Chapter 13: Fisheries and Aquaculture

Lead Authors
Hjalmar Vilhjálmsson, Marine Research Institute, Iceland
Alf Håkon Hoel, University of Tromsø, Norway
Contributing Authors
Sveinn Agnarsson, University of Iceland, Iceland
Ragnar Arnason, University of Iceland, Iceland
James E. Carscadden, Fisheries and Oceans Canada, Canada
Arne Eide, University of Tromsø, Norway
David Fluharty, University of Washington, USA

E.F. Vedrova, V.N. Sukachev Institute of Forest Research, RAS, Russia
Martin Wilmking, Lamont-Doherty Earth Observatory, USA

Chapter 15: Human Health

Lead Authors
Jim Berner, Alaska Native Tribal Health Consortium, USA
Christopher Furgal, Laval University, Canada
Contributing Authors:
Peter Bjerregaard, National Institute of Public Health, Denmark
Mike Bradley, Alaska Native Tribal Health Consortium, USA
Tine Curtis, National Institute of Public Health, Denmark
Ed De Fabo, George Washington University, USA
Juhani Hassi, University of Oulu, Finland
William Keatinge, Queen Mary and Westfield College, UK
Siv Kvernmo, University of Tromsø, Norway
Simo Nayha, University of Oulu, Finland
Hannu Rintamaki, Finnish Institute of Occupational Health, Finland
John Warren, Alaska Native Tribal Health Consortium, USA

Chapter 16: Infrastructure: Buildings, Support Systems, and Industrial Facilities

Lead Author
Arne Instanes, Instanes Consulting Engineers, Norway
Contributing Authors
Oleg Anisimov, State Hydrological Institute, Russia
Lawson Brigham, U.S. Arctic Research Commission, USA
Douglas Goering, University of Alaska Fairbanks, USA
Lev N. Khrustalev, Moscow State University, Russia
Branko Ladanyi, École Polytechnique de Montreal, Canada
Jan Otto Larsen, Norwegian University of Science and Technology, Norway
Consulting Authors
Orson Smith, University of Alaska Anchorage, USA
Amy Stevermer, University of Colorado at Boulder, USA
Betsy Weatherhead, University of Colorado at Boulder, USA
Gunter Weller, University of Alaska Fairbanks, USA

Chapter 17: Climate Change in the Context of Multiple Stressors and Resilience

Lead Authors
James J. McCarthy, Harvard University, USA
Marybeth Long Martello, Harvard University, USA
Contributing Authors
Robert Corell, American Meteorological Society and Harvard University, USA
Noelle Eckley Selin, Harvard University, USA
Shari Fox, University of Colorado at Boulder, USA
Grete Hovelsrud-Broda, Centre for International Climate and Environmental Research, Norway
Svein Disch Mathiesen, Norwegian School of Veterinary Science and Nordic Sámi Institute, Norway
Colin Polsky, Clark University, USA
Henrik Selin, Boston University, USA
Nicholas J.C. Tyler, University of Tromsø, Norway
Consulting Authors
Kirsti Strøm Bull, University of Oslo and Nordic Sámi Institute, Norway
Inger Maria Gaup Eira, Nordic Sámi Institute, Norway
Nils Isak Eira, Fossbakken, Norway

Siri Eriksen, Centre for International Climate and Environmental
    Research, Norway
Inger Hanssen-Bauer, Norwegian Meteorological Institute, Norway
Johan Klemet Kalstad, Nordic Sámi Institute, Norway
Christian Nellemann, Norwegian Nature Research Institute, Norway
Nils Oskal, Sámi University College, Norway
Erik S. Reinert, Hvasser, Tønsberg, Norway
Douglas Siegel-Causey, Harvard University, USA
Paal Vegar Storeheier, University of Tromsø, Norway
Johan Mathis Turi, Association of World Reindeer Herders, Norway

Chapter 18: Summary and Synthesis of the ACIA

Lead Author
Gunter Weller, University of Alaska Fairbanks, USA
Contributing Authors
Elizabeth Bush, Environment Canada, Canada
Terry V. Callaghan, Abisko Scientific Research Station, Sweden; Sheffield
    Centre for Arctic Ecology, UK
Robert Corell, American Meteorological Society and Harvard
    University, USA
Shari Fox, University of Colorado at Boulder, USA
Christopher Furgal, Laval University, Canada

    Norway
James D. Reist, Fisheries and Oceans Canada, Canada
Aapo Tanskanen, Finnish Meteorological Institute, Finland
John E. Walsh, University of Alaska Fairbanks, USA
Betsy Weatherhead, University of Colorado at Boulder, USA
Frederick J. Wrona, National Water Research Institute, Canada

Biographies

Lead authors

Dr. James Berner graduated from Oklahoma University Medical School in 1968 and spent three years in the U.S. Navy Medical Corps. He completed residency training and is board certified in Internal Medicine and Pediatrics. Dr. Berner has practiced medicine in the Alaska Native health care system since 1974 and has served as Director of Community Health for the Alaska Native health care system and part-time clinician since 1984. Dr. Berner currently directs the Alaska Native Traditional Food Safety Monitoring program, which assesses contaminant and micronutrient levels in pregnant Alaska Native women, and evaluates health effects in mothers and newborn infants. He has been the key national expert for the U.S. in the Human Health Expert Group of the Arctic Monitoring and Assessment Programme, a working group of the Arctic Council, since 1999.

Professor Terry V. Callaghan (B.Sc. Manchester University, Ph.D. Birmingham University, Ph.D. (honorary) Lund University, Ph.D. (honorary) Oulu University, D.Sc. Manchester University, and member of the Royal Swedish Academy of Sciences) has been involved in arctic ecological research for 37 years, and has worked in all eight arctic countries. He has been Director of the Royal Swedish Academy of Sciences' Abisko Scientific Research Station in the Swedish subarctic since 1996 and is concurrently Professor of Arctic Ecology at the University of Sheffield, UK, and the University of Lund, Sweden. His research focuses on the relationships between the arctic environment and the ecology of arctic plants, animals, and ecosystem processes, including ecological responses to changes in climate, atmospheric carbon dioxide concentrations, and ultraviolet (UV)-B radiation. Professor Callaghan is a member of the United Nations Environment Programme's expert panel on Stratospheric Ozone Depletion Effects, and was a lead author for the ecosystems chapter in the 1990 IPCC assessment of climate change, the polar chapter of the fourth IPCC assessment of climate change, and the polar chapter in the Millennium Ecosystem Assessment. Dr. Callaghan has initiated and chaired several international research groups within the International Arctic Science Committee, and is co-ordinator of SCANNET (Scandinavian and north European Network of Terrestrial Field Bases).

Dr. Shari Fox (BES, MES University of Waterloo, Canada; Ph.D. University of Colorado, Boulder) currently holds a post doctoral position at Harvard University as part of the U.S. National Oceanic and Atmospheric Administration Postdoctoral Program in Climate and Global Change (2003–2005). In 2006, she will join the National Snow and Ice Data Center at the University of Colorado as a research scientist. Dr. Fox has been working with Inuit in Nunavut, Canada, for over a decade. Her research focuses on Inuit knowledge of climate and environmental change and includes work on the documentation of Inuit observations, collaborative research approaches, finding linkages between Inuit and scientific knowledge, and experimenting with creative research products for use in local communities. Dr. Fox has been a consultant for local communities and the Government of Nunavut in efforts to develop a climate change strategy for Nunavut. In 2005, she was appointed to the National Academy of Sciences study committee on designing an Arctic Observing Network and is part of the Coastal Working Group for the second International Conference on Arctic Research Planning (ICARP II). Dr. Fox lives in Clyde River, an Inuit community on Baffin Island, Nunavut.

Dr. Chris Furgal (B.Sc. University of Western Ontario; M.Sc. and Ph.D. University of Waterloo) is a senior researcher at the Public Health Research Unit, Laval University Research Hospital and a research professor in the Department of Political Science at Laval University. For the past 13 years, he has been conducting multidisciplinary research in the biological, social, and health sciences on environmental health issues such as climate change and environmental contaminants, and their management and communication in the circumpolar North in cooperation with Inuit and other Indigenous organizations. He is a lead author for the polar chapter in the fourth IPCC assessment of climate change. Dr. Furgal is a member of the Canadian Federal Northern Contaminants Program Management Committee, the Nunavik Nutrition and Health Committee, and is Co-Director of the recently established Nasivvik Centre for Inuit Health and Changing Environments at Laval, one of eight federally funded centers for aboriginal health research and training in Canada.

Professor Alf Håkon Hoel (cand. polit. University of Oslo) teaches political science at the University of Tromsø, Norway. His research concerns international ocean governance issues and arctic affairs. He has published widely on the management of natural resources and the environment. Current projects include analyses of global change and fisheries, the experience of various countries with their resource management regimes, and the relationship between trade regimes and resource management regimes. He is also involved with the Arctic Monitoring and Assessment Programme's assessment on Oil and Gas in the Arctic. Professor Hoel has served as vice-president of the International Arctic Science Committee, and is a member of the Scientific Steering Committee of the Institutional Dimensions of Global Environmental Change program and the board of the Institute of Marine Research, Bergen.

Dr. Henry P. Huntington (A.B. Princeton University, M.Phil. and Ph.D. University of Cambridge) is an independent researcher in Eagle River, Alaska. His research has documented traditional ecological knowledge of beluga whales in Alaska and Russia, examined Iñupiat Eskimo knowledge and use of sea ice in Alaska, evaluated U.S. involvement in the Arctic Council, analyzed the co-management practices of the Alaska Beluga Whale Committee, studied the adaptation of wildlife management to incorporate subsistence hunting practices, and assessed the interactions of humans and forest fires in interior Alaska. This work has been funded by the National Science Foundation (NSF), the Trust for Mutual Understanding, the Exxon Valdez Oil Spill Trustee Council, the National Marine Fisheries Service, the Alaska Beluga Whale Committee, the Marine Mammal Commission, and other agencies and organizations. Dr. Huntington has also been involved as a researcher and writer in a number of international research programs, such as the Arctic Monitoring and Assessment Programme and the Program for the Conservation of Arctic Flora and Fauna. He was a member of the U.S. Polar Research Board from 1999 to 2005 and president of the Arctic Research Consortium of the United States from 2001 to 2003.

Dr. Arne Instanes (M.Sc. and Ph.D. Norwegian Institute of Technology, University of Trondheim) has worked with cold regions engineering for the last 15 years. He has work experience from research institutes and universities in Norway (SINTEF Geotechnical Engineering, Trondheim; Norwegian Geotechnical Institute, Oslo; University Centre in Svalbard, Longyearbyen) and Canada (University of Alberta, Edmonton). Dr. Instanes is currently vice-president of OPTICONSULT consulting engineers in Bergen, and director of Instanes Svalbard AS in Longyearbyen. His research on cold regions engineering includes work on stress-strain relationships in frozen soil, snow, and ice, thermal analysis of engineering structures, and the effect of pollution on the physical and mechanical properties of frozen soils. Dr. Instanes is co-chairman of the International Permafrost Association's Working Group on Permafrost Engineering and is a member of the International Society of Soil Mechanics and Geotechnical Engineering Technical Committee No. 8 on Frost.

Dr. Glenn Patrick Juday (B.S. Purdue University, Ph.D. Oregon State University) is currently Professor of Forest Ecology and Director of the Tree-Ring Laboratory in the Forest Sciences Department of the School of Natural Resources and Agricultural Sciences at the University of Alaska Fairbanks, where he has worked since 1981. His research specialties include climate change, tree-ring studies, biodiversity and forest management, and forest development following fire. He is currently a co-principal investigator in the NSF-supported Bonanza Creek Long-Term Ecological Research site, and has been on the science steering board of the Center for Global Change at the University of Alaska since its founding. Dr. Juday contributed to the U.S. National Climate Change regional assessment regional reports for Alaska and elsewhere. Dr. Juday teaches conservation biology and wilderness ecosystem management. He has served as science advisor for several television programs and in-depth news articles on climate warming in the United States, Europe, and Japan. He conducted research in the office of the vice president for science of The Nature Conservancy in 1988, and served as president of the Natural Areas Association for four years. Dr. Juday was recognized for outstanding accomplishments as the Chair of the Society of American Foresters Forest Ecology Working Group in 2000.

Professor Erland Källén (B.Sc. and Ph.D. Stockholm University, Sweden) is a professor of dynamic meteorology at the Department of Meteorology, Stockholm University and is presently head of department. His research areas are numerical weather prediction and climate modeling. He has contributed to the understanding of long wave

dynamics in the atmosphere as well as methods for data assimilation in the field of numerical weather prediction. Dr. Källén contributed to the 2001 IPCC assessment of climate change, both as reviewer and participant in workshops and meetings. Dr. Källén was the first director of the Swedish Regional Climate Modelling Programme (SWE-CLIM) and his present activities include research on climate processes relevant to the Arctic. His positions on scientific bodies include: president of the Swedish Geophysical Society, chairman of the scientific advisory committee of the European Centre for Medium-Range Weather Forecasts, chairman of the Swedish committee to the World Climate Research Programme/ International Geosphere–Biosphere Programme, editorial board member of the journal Tellus, board member of the Swedish Meteorological and Hydrological Institute, member of a mission advisory group for the European Space Agency's Earth Explorer Atmospheric Dynamics mission. His main research interest is the large scale dynamics of the atmosphere and its applications to climate dynamics and weather prediction.

Dr. Vladimir M. Kattsov (M.Sc. Leningrad Hydrometeorological Institute; M.Sc. St. Petersburg State University; M.A. Kalinin State University, Ph.D. Leningrad Hydrometeorological Institute) is in his 17th year as a research scientist at the Voeikov Main Geophysical Observatory of the Russian Federal Service for Hydrometeorology and Environmental Monitoring, St. Petersburg. Since 2000, he has been head of the Department of Dynamic Meteorology. Dr. Kattsov's research includes global climate 3D modeling with a focus on polar climate dynamics. He was a lead author for the 2001 IPCC Working Group I report, and is currently a lead author for the chapter on model evaluation in the fourth IPCC assessment of climate change. Since 2000, Dr. Kattsov has been a member of the World Climate Research Programme's Working Group on Numerical Experimentation. He is a member of the Climate Commission of the Russian National Geophysical Committee, and a member of the Russian National Council on the WCRP project "Climate and Cryosphere".

Dr. David R. Klein (B.S. University of Connecticut, M.S. University of Alaska, Ph.D. University of British Columbia) was employed by the U.S. Fish and Wildlife Service prior to Alaskan statehood, and by the Alaska Department of Fish and Game immediately after statehood. He was leader of the Alaska Cooperative Wildlife Research Unit at the University of Alaska from 1962 to 1992 when he was appointed senior scientist with the Alaska Cooperative Fish and Wildlife Research Unit until his retirement in 1997. Dr. Klein spent sabbatical-type leaves undertaking research on roe deer in Denmark, wild reindeer in Norway (via a Fulbright Grant), and impala and blesbok in South Africa, and has been involved in other collaborative research in Canada, Greenland, Scandinavia, Siberia, and Portugal. Dr. Klein's research interests have focused on arctic and alpine ecology and habitat relationships of caribou, muskoxen, and other herbivores, assessment of impacts of northern development, and sustainability of arctic ecosystems. He serves on the Board of the Arctic Research Consortium of the United States and is currently Professor Emeritus with the Institute of Arctic Biology and the Department of Biology and Wildlife at the University of Alaska Fairbanks.

Professor Harald Loeng is head of the research group Oceanography and Climate at the Institute of Marine Research in Bergen and is adjunct professor at the University of Tromsø, Norway. He was responsible for the research program on Fish and Climate at IMR and has been head of the Norwegian Marine Data Centre. His main research interest has been climate change and variability and its impact on the marine ecosystem. His positions on scientific bodies include: chair of the Hydrography Committee, the Oceanography Committee, and the Consultative Committee of the International Council for the Exploration of the Sea (ICES); chair of the Norwegian National Committee on Polar Research under the Research Council of Norway; and vice-chair of the Arctic Ocean Science Board. Dr. Loeng has been the Norwegian member of the ICES Advisory Committee of Marine Environment. He was a lead author for the chapter on marine pathways in the 1998 assessment on Arctic Pollution Issues by the Arctic Monitoring and Assessment Programme. He has been an editorial board member for the Journal of Fisheries Oceanography since its beginning.

Dr. Marybeth Long Martello (B.S. and B.A. University of Connecticut, M.S. and Ph.D. Massachusetts Institute of Technology) is a research fellow in Harvard University's Science, Technology, and Society Program. Her research examines global change science and governance, and includes projects on scientific and political dimensions of vulnerability analysis, framing, analysis and representation of climate change impacts, scientific and intergovernmental efforts to address dryland degradation, local knowledge and traditional knowledge in the context of environmental science and policymaking, and corporate approaches to sustainability. She was formerly a research associate with the Kennedy School's Sustainability Systems Project, a policy fellow with the American Meteorological Society, a fellow with the Global Environmental

Assessment Project, and a fellow with an NSF-funded project on Sustainable Knowledge for the Global Environment. Dr. Martello is a contributor to the United Nations Environment Programme's fourth Global Environmental Outlook Report, and has worked as an environmental consultant. She has authored a number of journal articles and book chapters and is co-editor of Earthly Politics: Local and Global in Environmental Governance.

Professor Gordon McBean (M.Sc., McGill University; Ph.D., University of British Columbia) has been active in studies of the atmosphere and weather and climate systems for over 35 years. Dr. McBean was a scientist in Environment Canada and then moved to the Institute of Ocean Sciences. In 1988, he became Professor of Atmospheric and Oceanic Sciences at the University of British Columbia and chair of the WMO-IOC-ICSU Joint Scientific Committee for the World Climate Research Program. As chair, he initiated the Arctic Climate System Study (ACSyS), and other major programs. In 1994, he was appointed Assistant Deputy Minister for the Meteorological Service of Environment Canada, with overall responsibility for weather, climate, sea ice, and water sciences and services in the Canadian government. Since leaving government in 2000, he has been appointed professor in the Institute for Catastrophic Loss Reduction at the University of Western Ontario and Chair of the Board of Trustees for the Canadian Foundation for Climate and Atmospheric Sciences. Dr. McBean is theme leader for the Canadian ArcticNet research program, an integrated study of the coastal Canadian Arctic in the context of climate change. He has been elected a Fellow of the Royal Society of Canada, the American Meteorological Society, and the Canadian Meteorological and Oceanographic Society.

Dr. James J. McCarthy (B.S. Gonzaga University, Ph.D Scripps Institution of Oceanography) is Alexander Agassiz Professor of Biological Oceanography and Head Tutor for degrees in Environmental Science and Public Policy at Harvard University. He recently completed a two-decade term as Director of Harvard University's Museum of Comparative Zoology. His research interests concern the regulation of marine plankton productivity, and in recent years have focused on regions that are strongly affected by seasonal and interannual variation in climate. He has written many scientific papers, and currently teaches courses on biological oceanography, biogeochemical cycles, marine ecosystems, and global change and human health. Dr. McCarthy has served on many national and international planning committees, advisory panels, and commissions relating to oceanography, polar science, and the study of climate and global change. From 1986 to 1993, he chaired the International Geosphere–Biosphere Program. He was the founding editor for the American Geophysical Union's Global Biogeochemical Cycles. He was a convening lead author for the 1990 IPCC Working Group I report, and was co-chair of the 2001 IPCC Working Group II. He has been elected a Fellow of the American Association for the Advancement of Science, a Fellow of the American Academy of Arts and Sciences, and a Foreign Member of the Royal Swedish Academy of Sciences.

Professor Mark Nuttall (MA University of Aberdeen, Ph.D. University of Cambridge) holds the Henry Marshall Tory Chair of Anthropology at the University of Alberta and is Honorary Professor of Sociology at the University of Aberdeen. His work in the Arctic and North Atlantic is mainly concerned with environmental change and resource use issues in rural and coastal communities, depopulation and migration, climate change impacts on indigenous peoples and their livelihoods, the human dimensions of global environmental and sustainability issues, and historical ecology. He has worked extensively in Greenland, Alaska, Canada, and Scotland. Dr. Nuttall is author of Arctic Homeland: Kinship, community and development in northwest Greenland (University of Toronto Press, 1992), White Settlers: The impact of rural repopulation in Scotland (Routledge, 1996), and Protecting the Arctic: Indigenous peoples and cultural survival (Routledge, 1998); editor of the three-volume Encyclopedia of the Arctic (Routledge, 2005); and co-editor of The Arctic: Environment, people, policy (Taylor and Francis, 2000), Cultivating Arctic Landscapes: Knowing and managing animals in the circumpolar North (Berghahn, 2004), and The Russian North in Circumpolar Context (2003).

Dr. Terry D. Prowse (B.E.S. University of Waterloo, M.Sc. Trent University, Ph.D. University of Canterbury) holds an Environment Canada Research Chair and Professorship in Geography at the Water and Climate Impacts Research Centre, University of Victoria, investigating the impacts of climate on water resources. As a senior scientist with Environment Canada, he also heads a research program for the National Water Research Institute investigating the impacts of climate on hydrology and aquatic ecosystems. He was a lead author (chapters on the cryosphere, ecosystems, and polar regions) for the 1995 and 2001 IPCC assessments of climate change, and has a similar position for the 2007 IPCC assessment of the Arctic and Antarctic. His positions on scientific bodies include: President of the Canadian Geophysical Union, including the Hydrology Section; Canadian government representative

for the UNESCO International Hydrologic Programme; Canadian Member of the International Association for Hydraulic Research-Ice; editorial board member for the journal Hydrological Processes, and associate editor for the Journal of Cold Regions Engineering. His main research interest is the impact of climate change on water resources and freshwater ecosystems, particularly in cold regions.

Dr. James (Jim) D. Reist (B.Sc. University of Calgary, M.Sc. University of Alberta, Ph.D. University of Toronto) is in his 22nd year as a research scientist in the Arctic Research Division at Fisheries and Oceans Canada, Central and Arctic Region, Winnipeg, where he has led the Arctic Fish Ecology and Assessment Research Section since 1989. His research addresses biodiversity of northern Canadian fishes using genetic, morphological, and ecological approaches with particular emphasis on chars and whitefishes. In addition to documenting fish diversity, biogeography, and understanding their roles in the structure and function of both arctic freshwater and marine ecosystems, his research addresses effects of anthropogenic activities such as exploitation, industrial development, and climate change. Dr. Reist has been active in the Conservation of Arctic Flora and Fauna working group of the Arctic Council, as well as in national and international programs to assess human impacts on fish in the Arctic. He has had adjunct status at several Canadian universities where he has supervised or co-supervised a number of graduate students researching northern fish biology and ecology. He has authored or co-authored over 80 scientific publications in both the primary literature and government publication series.

Amy J. Stevermer (M.S. Oregon State University) has been involved in research related to the transfer of radiation in the earth's atmosphere for more than a decade. Throughout her employment as an associate scientist at the University of Colorado at Boulder, she has contributed to projects focused on understanding the various parameters, including stratospheric aerosol and ozone, that affect UV radiation reaching the earth's surface. She has worked on data analysis and public outreach issues for the U.S Environmental Protection Agency's Ultraviolet Radiation Monitoring Network and has given talks on UV monitoring and effects studies at faculty workshops and national conferences.

Aapo Tanskanen (M.Sc. Lic.Tech. Helsinki University of Technology) is the head of the UV radiation research group at the Finnish Meteorological Institute. His research includes work on UV measurement techniques, radiative transfer modeling and development of methods for estimating surface UV irradiance using satellite data. He is a member of the Ozone Monitoring Instrument science team.

Professor Michael B Usher (B.Sc. and Ph.D. Edinburgh University, Honorary Doctorate University of Stirling) began his career at the University of York, with teaching and research interests in soil biodiversity and nature conservation. He undertook sabbatical periods to establish a termite research group in Ghana and to work on the soil mites and springtails in Antarctica. From 1991 until he retired he was chief scientist at Scottish Natural Heritage, the government's countryside and conservation agency in Scotland. In this role, as well as leading a large team of scientists, he was actively involved with advice to government ministers. Dr. Usher is a chartered biologist, a Fellow of the Institute of Biology, a Fellow of the Royal Entomological Society, and was elected a Fellow of the Royal Society of Edinburgh (Scotland's National Academy of Science & Letters) in 1999. Dr. Usher was awarded an OBE in the 2001 New Year Honour's List. Over the last few years he has chaired the U.K.'s Soil Biodiversity Research Programme, and has been active in the Scottish Biodiversity Forum and the Council of Europe; he is also a Trustee of the Royal Botanic Garden Edinburgh and the Woodland Trust, and continues to teach aspects of biodiversity conservation.

Dr. Hjálmar Vilhjálmsson (B.Sc. University of Glasgow, Ph.D. University of Bergen) has spent much of his career based at the Marine Research Institute in Reykjavík, initially working on operational fisheries research, namely the design and execution of surveys of pelagic fish migrations, abundance, and catchability, and on the environmental variables that affect them. The purpose of this work was to locate areas rich in target species, to predict future migrations and catchability, and to keep the fishing fleet informed. By necessity, the nature of his work changed to abundance assessments of these stocks and advising on their sustainable exploitation. He has been the senior pelagic fisheries biologist at the Marine Research Institute since 1990. Dr. Vilhjálmsson has been a member and vice-chairman of the board of the Icelandic Fisheries Fund, a long-term member of the ICES Northern Pelagic and Blue Whiting Working Group, and was appointed to serve on a special committee, organized by the National Research Council of Iceland, for evaluating existing fisheries science activities in Iceland and advising on research priorities. He is a member of the Icelandic Science Academy.

Dr. John Walsh (B.A. Dartmouth College, Ph.D. Massachusetts Institute of Technology) is a President's Professor of Global Change at the University of Alaska Fairbanks. He is also the Director of the Cooperative Institute for Arctic Research and the Center for Global Change at the University of Alaska. His research has addressed arctic climate weather variability, with an emphasis on sea ice variability and the role of sea ice and snow cover in weather and climate. His work has also included evaluations of global climate model simulations of the Arctic. Dr. Walsh is a lead author for the polar regions in the fourth IPCC assessment. He is a member of the Polar Research Board and a panel chair for the Study of Environmental Arctic Change (SEARCH). Before joining the University of Alaska, he spent 30 years on the faculty of the University of Illinois, where he taught courses on weather and climate. He co-authored the textbook, Severe and Hazardous Weather, and is an associate editor of the Journal of Climate.

Professor Gunter Weller (Ph.D. University of Melbourne) is Professor of Geophysics Emeritus of the University of Alaska Fairbanks. His early research concerned climate change and its impacts in both the Arctic and the Antarctic. He has been program manager of the NSF's polar programs in meteorology, project manager of the NOAA-BLM Outer Continental Shelf Environmental Assessment Program in the Arctic, project director of the NASA-University of Alaska SAR Facility, and deputy director of the UAF Geophysical Institute. Among many scientific committee assignments he was the president of ICSU's International Commission on Polar Meteorology and chaired the U.S. National Research Council's Polar Research Board. He recently retired as the director of the Center for Global Change and Arctic System Research and director of the NOAA-UAF Cooperative Institute for Arctic Research and now lives in Australia. Dr. Weller was Executive Director of the ACIA for the last four years.

Dr. Frederick Wrona (B.Sc. and Ph.D. University of Calgary) is currently the Director of the Aquatic Ecosystems Impacts Research Branch, National Water Research Institute (Environment Canada) and is a professor in the Department of Geography, University of Victoria. Dr. Wrona has conducted and managed interdisciplinary aquatic ecosystem research for over 23 years, focusing on the ecology and eco-hydrology of cold-regions aquatic ecosystems. His research interests include understanding and predicting the impacts of climate variability/change on the structure and function of cold-regions aquatic ecosystems, identifying mechanisms responsible for the observed patterns of dynamics in aquatic predator-prey systems, assessing the ecotoxicology of aquatic organisms to contaminant stressors, and assessing the impacts of human developments on the health and sustainability of northern aquatic systems. He has served as the Science Director for the Northern River Basins Study and is currently involved with numerous national and international scientific and advisory committees related to the development and implementation of northern hydrological and ecological research programs (e.g., contributing author to the 2007 IPCC Working Group II assessment of the polar regions and the 2nd International Conference on Arctic Research Planning, Environment Canada's Northern Working Group). Dr. Wrona has a strong interest in science-policy linkages and is currently the Head and Chief Delegate for the Canadian National Committee for the UNESCO International Hydrological Programme.

Additional Members of the ACIA Implementation Team[5]

Dr. Robert W. Corell (B.S., M.S., Ph.D., Case Western Reserve University and MIT) joined the National Science Foundation (NSF) in 1987 as Assistant Director for Geosciences where for over 12 years he oversaw the Atmospheric, Earth, and Ocean Sciences and the global change programs of the NSF. While there, Dr. Corell chaired the National Science and Technology Council's committee that oversees the U.S. Global Change Research Program, and the international committee of government agencies funding global change research. He was also chair and principal U.S. delegate to many international bodies with interests in and responsibilities for climate and global change research programs. Dr Corell is currently a Senior Fellow at the Policy Program of the American Meteorological Society and is actively engaged in research concerned both with the science of global change and with the interface between science and public policy, particularly research activities focused on global and regional climate change and related environmental issues, and science to facilitate understanding of vulnerability and sustainable development. He co-chairs an international strategic planning group on harnessing science, technology, and innovation for sustainable development, and is the lead for an international partnership to better understand and plan for a transition to hydrogen for several nations, currently focused on Iceland, India, and the eight Arctic nations. He is leading a research project to explore methods, models, and conceptual frameworks for vulnerability research, analysis, and assessment – the current focus of which is on vulnerabilities of indigenous communities in the Arctic. Dr Corell was recently invited to join the Washington Advisory Group, LLC to work on the industry dimension of the climate issue.

---

[5]Entries for Terry Callaghan, Gordon McBean, and Gunter Weller may be found under "Lead authors"

Dr. Pål Prestrud (Master degree and Ph.D. University of Oslo) has been involved for the last 25 years in environmental research and management in the Arctic, with a special research interest in population dynamics of polar mammals and their physiological adaptation to the harsh polar conditions. Dr. Prestrud is currently Director of the Centre for Climate Research at the University of Oslo. He has been Director of Research for a number of years at the Norwegian Polar Institute, and has served as deputy director general in the Norwegian Ministry of Environment where he headed the Section on Polar Affairs and Cooperation with Russia. Dr. Prestrud has been involved in several environmental impact assessments conducted in the Norwegian Arctic over the last 20 years.

Lars-Otto Reiersen graduated in marine biology from the University of Oslo, Norway. He then worked at the University of Oslo for several years conducting research on basic processes in marine fish and the effects of oil and other contaminants. He later worked for the Norwegian State Pollution Control Authority dealing with the environmental regulation of shipping and oil and gas activities (exploration and exploitation) in the seas around Norway and at Svalbard. He was involved in the work of the Oslo and Paris Commissions and the London Dumping Commission, especially in relation to the testing of chemicals to be used offshore and chemical and biological monitoring of the marine environment. He chaired the group that made the assessment of the Pollution of the North Sea under the North Sea Task Force and was involved in the establishment and implementation of the Arctic Environmental Protection Strategy and the Arctic Council. Since 1992, he has been the Executive Secretary for the Arctic Monitoring and Assessment Programme.

Jan Idar Solbakken (M.Sc. University of Tromsø) has worked at Saami University College, Norway for the last 13 years as an assistant professor in biology. From 2000 to 2003 he was Dean at Saami University College. He has represented the Saami Council, one of the Permanent Participants in the Arctic Council, within AMAP working groups since 1994. He also represented the Saami Council within the AMAP Assessment Steering Group during the first AMAP assessment of Arctic Pollution Issues.

Dr. Patricia A. Anderson (B.Sc. University of Iowa, M.A. Dalhousie University, Ph.D. New York University) has 18 years experience researching polar issues and managing polar science programs at the NSF and the University of Alaska Fairbanks. She was Executive Director of the U.S. Antarctic Program Safety Review Panel, an NSF activity that involved researching the history of U.S. exploration and science in Antarctica and the safety of these operations, and co-authoring the panel's report. She spent four years coordinating federal interagency programs on global climate change. Dr. Anderson's 12 years of experience at the University of Alaska Fairbanks involved the management of several arctic research and education activities, including the establishing of a competitive student research grant program, expanding participation of a wide range of stakeholder groups in assessing the impacts of climate change on Alaska, and facilitating interdisciplinary arctic system research through science management of the NSF Arctic System Science Land-Atmosphere-Ice Interactions program. In her capacity as Deputy Executive Director of the ACIA Secretariat, she has been responsible for coordinating all ACIA activities.

Elizabeth Bush (M.Sc. and M.A. University of Toronto) is a member of the Science Assessment and Integration Branch of Environment Canada, whose mandate it is to provide science advice and to coordinate science assessment activities on atmospheric issues. She has been involved in science assessment activities for many years, working first as an air quality advisor during which time she participated in Canadian national assessments of particulate matter and ground-level ozone. She currently works as a climate change science advisor and was the focal point in Canada for Canadian participation in the ACIA.

Paul Grabhorn is a communications consultant and photographer with 22 years of experience producing publications and campaigns on the subjects of global change, humanitarian action, and environmental research. A particular area of expertise is in the visual communication of complex subjects. His background in human ecology provides his work with a systems view and a synthesis perspective. Some of Grabhorn Studio's productions include: The U.S. National Assessment – Climate Change Impacts on the United States, Global Energy Technology Strategy: Addressing Climate Change, White House Conference on Science and Economics related to Global Change, National Energy Strategy, National Space Council Annual Reports, Coastal America campaign materials, Global Stewardship Brochure (White House), Army Corps of Engineers Environmental Stewardship Campaign, Defense and the Environment Initiative (US Army), GLOBE - Global Learning and Observations to Benefit the Environment (White House) – US Global Change Research Program – annual reports: Our Changing Planet, CIESIN; Understanding the Human Dimensions of Global Change, US Army Corps of Engineers recruitment and outreach materials, Government Buy Recycled Initiative, Technology for a Sustainable Future (White House), Bridge to a Sustainable Future: National Environmental Technology Strategy (White House), Sustainable America: A New Consensus, Picturing Climate's Complexity, People on War campaign (International Committee of the Red Cross), So Why! Music goes to war campaign (ICRC). Paul Grabhorn has also undertaken photographic documentary missions for the International Committee of the Red Cross in many locations: Somalia, Bosnia, Rwanda, Azerbaijan, Georgia, Abkhazia, Armenia, Ngorni Kharabakh, Chechnya, Cambodia, Colombia, Philippines, Croatia, Nepal, Burundi, Guatemala, Mali, Angola, South Africa, Kenya, and Liberia among others.

Susan Joy Hassol is a researcher and writer with 20 years experience in global change science. Known for her ability to translate science into English, she synthesizes information from across the spectrum of scientific disciplines, and makes complex issues accessible to policymakers and the public. She was a lead author of Climate Change Impacts on the United States, the synthesis report of the U.S. National Assessment of the Consequences of Climate Change. Susan authored a chapter on energy efficiency in a book entitled Innovative Energy Strategies for CO_2 Stabilization (Cambridge University Press, 2002). She wrote a feature article entitled "A Change of Climate," in Issues in Science and Technology, a journal of the National Academy of Sciences, focusing on the actions of U.S. states, localities, and corporations in mitigating climate change. She has also written and edited numerous articles, papers, and books for organizations including the United Nations Environment Programme, the Scientific Committee on Problems of the Environment, and the Inter-American Institute for Global Change Research. She has served as Environment Fellow for the Aspen Institute and as Research Associate and Director of Communications for the Aspen Global Change Institute.

Dr. Michael C. MacCracken (B.S.E. Princeton University; Ph.D. University of California Davis) is Senior Scientist for Climate Change with the Climate Institute in Washington, DC. For 34 years, he was employed by the Lawrence Livermore National Laboratory, where his research included numerical modeling of various natural and anthropogenic causes of climate change and of factors affecting air quality in the Bay Area and northeastern United States. For the latter part of this period, Dr. MacCracken was on assignment with the interagency Office of the U.S. Global Change Research Program, serving for different periods as executive director of the Office and of its National Assessment Coordination Office. He also coordinated the U.S. Government technical review of the IPCC assessments. Dr. MacCracken is currently president of the International Association of Meteorology and Atmospheric Sciences and serves on the executive committees of the International Union of Geodesy and Geophysics and the Scientific Committee for Oceanic Research.

ACIA Science Editors

Lelani Arris (B.Sc. University of Vermont, M.Sc. Massachusetts Institute of Technology) has more than 14 years experience writing and editing technical and popular publications about climate change, ozone depletion, and other environmental science topics. She was editor of the bi-weekly newsletter Global Environmental Change Report for five years, senior editor of the quarterly magazine Global Change for three years, and has also written or edited publications for the Canadian Climate Impacts and Adaptation Research Network, the U.S. Global Change Research Program, and the British Columbia Ministry of Forests, among others.

Dr. Carolyn Symon (B.Sc. Loughborough University, M.Sc. Kings College London, Ph.D. Lancaster University and Proudman Oceanographic Laboratory) is a science editor specializing in multi-authored environmental assessments prepared by intergovernmental bodies. For the last ten years most of her work has focused on marine-related and polar-related issues. Dr. Symon has undertaken work for the OSPAR Commission, the British Antarctic Survey, the Secretariat for the Fifth North Sea Conference, ICES, CCAMLR, and AMAP.

Professor Bill (O.W.) Heal (BSc., Ph.D. Durham University, Honorary Professor Edinburgh University, Fellow Hatfield College, Durham) is now retired. His early research on protozoa expanded into soil biology and decomposition then into ecosystems. In the 1970s he led the UK International Biological Programme at the Moor House upland site. This linked naturally into the IBP Tundra Biome through its sub-Arctic climate and to his involvement in international co-ordination and synthesis. As Director of the Institute of Terrestrial Ecology he was responsible for a wide range of pure and applied national and international research. He led the EU Arctic Terrestrial Ecosystem Research project which helped to integrate arctic research and spawned a series of new Arctic–Alpine projects. He subsequently chaired the Polar Sciences Committee of the Natural Environment Research Council, helped to initiate the University of the Arctic, and participated in CAFF and AMAP and in the US NSF and LTER programs.

Reviewers

This appendix lists those international experts selected by ACIA that were willing to review one or more chapters of this assessment. Most of the experts listed below reviewed at least two related chapters and a few reviewed several chapters. Many additional reviewers, not listed here, were selected through national reviews conducted by the arctic countries. Reviews were received from about 200 individuals in total.

Hans Alexandersson, Swedish Meteorological and Hydrological Institute
Leif Anderson, Göteborg University, Sweden
Robert Barbault, Institut d'Ecologie Fondamentale et Appliquee, France
Roger Barry, National Snow and Ice Data Center, USA
Esfir G. Bogdanova, Voeikov Main Geophysical Observatory, Russia
Jerry Brown, International Permafrost Association, USA
Margo Burgess, Geological Survey of Canada
John Calder, National Oceanic and Atmospheric Administration, USA
JoLynn Carroll, Akvaplan-niva AS, Norway
Tim Carter, Finnish Environment Institute
Richard Caulfield, University of Alaska Fairbanks
Nataly Ye. Chubarova, Moscow State University, Russia
Stewart Cohen, University of British Columbia, Canada
Andre Corriveau, Government of the Northwest Territories, Dept. of Health and Social Services, Canada
Robert Crawford, University of St. Andrews (Emeritus), UK
Yvon Csonka, University of Greenland
Jens Dahl, International Work Group for Indigenous Affairs, Denmark
Klaus Dethloff, Alfred Wegener Institute for Polar and Marine Research, Germany
Mark Dyurgerov, University of Colorado at Boulder, USA
Michael A.D. Ferguson, Dept. of Sustainable Development, Government of Nunavut, Canada
Craig Fleener, Gwich'in Council International, USA
Sven Haakanson, Jr., Alutiiq Museum, Kodiak, Alaska, USA
Don Hayley, EBA Engineering Consultants Ltd., Canada
Bill Heal, University of Durham, UK
Raino Heino, Finnish Meteorological Institute
Annika Hofgaard, Norwegian Institute for Nature Research, Norway
Ad H.L. Huiskes, Netherlands Institute of Ecology
George Hunt, University of California, Irvine, USA
Ingvar Jarle Huse, Institute of Marine Research, Norway
Satu Huttunen, University of Oulu, Finland
Trond Iversen, University of Oslo, Norway
Robert Jefferies, University of Toronto, Canada
Peter Jones, Bedford Institute of Oceanography, Canada
Eigil Kaas, Danish Meteorological Institute
Anders Karlqvist, Swedish Polar Research Secretariat
Roy Koerner, Geological Survey of Canada
Pirkko Kortelainen, Finnish Environment Institute
Eduard Koster, Utrecht University, Netherlands
Peter Kuhry, Stockholm University, Sweden
Manfred Lange, University of Muenster, Germany
Donald S. Lemmen, Natural Resources Canada

Pentti Mälkki, Finnish Institute of Marine Research
Svend Aage Malmberg, Marine Research Institute, Iceland
Michael McGeehin, Centers for Disease Control, USA
Richard McKenzie, National Institute of Water and Atmospheric Research, New Zealand
Mark Meier, University of Colorado at Boulder, USA
Jamie Morison, University of Washington, USA
Lars Moseholm, National Environmental Research Institute, Denmark
Ted Munn, University of Toronto, Canada
Aynslie Ogden, Northern Climate ExChange, Canada
Erling Ögren, Swedish University of Agricultural Sciences
Mats Olsson, Swedish University of Agricultural Sciences
Olav Orheim, Norsk Polarinstitutt, Norway
Jim Overland, Pacific Marine Environmental Laboratory/NOAA, USA
Chris Paci, Dene Nation, Canada
Gísli Pálsson, University of Iceland
Walter Parker, Circumpolar Infrastructure Task Force of the Arctic Council; the Northern Forum, USA
Geoff Petts, University of Birmingham, UK
Henning Rodhe, Stockholm University, Sweden
Odd Rogne, International Arctic Science Committee, Norway
Ursula Schauer, Alfred Wegener Institute for Polar and Marine Research, Germany
Frank Sejersen, University of Copenhagen, Denmark
Stepan G. Shiyatov, Institute of Plant and Animal Ecology, Russian Academy of Sciences
Oddvar Skre, Norwegian Forest Research Institute
Kimberly Strong, University of Toronto, Canada
Thora E. Thorhallsdottir, University of Iceland
Darin Toohey, University of Colorado at Boulder, USA
Reidar Toresen, Institute of Marine Research, Norway
Adrian Tuck, NOAA Aeronomy Laboratory, USA
Jay Van Oostdam, Health Canada
Patrick J. Webber, Michigan State University, USA
Martin Weinstein, 'Namgis First Nation, Canada
Jan Weslawski, Institute of Oceanology, Polish Academy of Sciences
Ed Wiken, Wildlife Habitat Canada
Ming-Ko Woo, McMaster University, Canada
Oran Young, University of California, Santa Barbara, USA
T. Kue Young, University of Toronto, Faculty of Medicine, Canada
Alexander Zhulidov, South Russian Regional Centre for Preparation and Implementation of International Projects
Francis Zwiers, Meteorological Service of Canada

Species Names

Latin name	Common name/descriptor

Birds

Aethia cristatella	crested auklet	*Fulmaris glacialis*	northern fulmar
Aethia psittacula	parakeet auklet	*Gallinago gallinago*	common snipe
Aethia pusilla	least auklet	*Gavia adamsii*	yellow-billed loon
Alca torda	razorbill	*Gavia arctica*	Arctic loon
Alle alle	little auk	*Gavia immer*	common loon/ great northern diver
Anas acuta	pintail	*Gavia pacifica*	Pacific loon
Anas americana	widgeon	*Gavia stellata*	red-throated loon
Anas crecca	common teal	*Grus americana*	whooping crane
Anas penelope	Eurasian wigeon	*Haematopus ostralegus*	Eurasian oystercatcher
Anas platyrhynchos	mallard	*Hydrobates pelagicus*	European storm petrel
Anser albifrons	white-fronted goose or "yellow legs"	*Lagopus lagopus*	willow grouse
A. a. flavirostris	Greenland white-fronted goose	*Lagopus mutus*	ptarmigan
Anser anser	greylag goose	*L. m. hyperboreus*	Svalbard ptarmigan
Anser brachyrhynchus	pink-footed goose	*Larus argentatus*	herring gull
Anser caerulescens	snow goose	*Larus canus*	mew gull
A. c. caerulescens	lesser snow goose	*Larus fuscus*	lesser black-backed gull
Anser canagicus	emperor goose	*Larus glaucescens*	glaucous-winged gull
Anser erythropus	lesser white-fronted goose	*Larus hyperboreus*	glaucous gull
Anser fabalis	bean goose	*Larus marinus*	great black-backed gull
A. f. fabialis	taiga bean goose	*Larus ridibundus*	black-headed gull
A. f. rossicus	tundra bean goose	*Limnodromus scolopaceus*	Long-billed dowitcher
Arenaria interpres	ruddy turnstone	*Limosa lapponica*	bar-tailed godwit
Asio flammeus	short-eared owl	*Limosa limosa*	black-tailed godwit
Aythya affinis	lesser scaup	*Loxia* spp.	crossbills
Aythya collaris	ring-necked duck	*Melanitta fusca*	white-winged scoter/ velvet scoter
Aythya marila	greater scaup	*Melanitta nigra*	black scoter
Aythya valisineria	canvasback duck	*Mergus merganser*	common merganser
Branta bernicla	Brent goose/ black brent	*Mergus serrator*	red-breasted merganser
B. b. bernicla	dark-bellied brent goose	*Morus bassanus*	northern gannet
B. b. hrota	light-bellied brent goose	*Motacilla alba*	white wagtail
Branta canadensis	Canada goose	*Numenius borealis*	Eskimo curlew
Branta leucopsis	barnacle goose	*Nyctea scandiaca*	snowy owl
Branta ruficollis	red-breasted goose	*Oceanodroma leucorhoa*	Leach's storm-petrel
Buteo spp.	raptors	*Oenanthe oenanthe*	northern wheatear
Buteo lagopus	rough-legged buzzard	*Pagophila eburnea*	ivory gull
Calcarius lapponicus	Lapland longspur	*Parus caeruleus*	blue tit
Calidris acuminata	sharp-tailed sandpiper	*Phalacrocorax aristotelis*	European shag
Calidris alba	sanderling	*Phalacrocorax carbo*	great cormorant
Calidris alpina	dunlin	*Phalacrocorax pelagicus*	pelagic cormorant
Calidris canutus	red knot	*Phalacrocorax perspicillatus*	Pallas's cormorant
C. c. canutus	red knot (Taymir population)	*Phalaropus fulicarius*	red phalarope/ grey phalarope
C. c. islandica	red knot (Nearctic population)	*Phalaropus lobatus*	northern phalarope/red-necked phalarope
Calidris ferruginea	curlew sandpiper	*Philomachus pugnax*	ruff
Calidris fuscicollis	white-rumped sandpiper	*Phylloscopus borealis*	Arctic warbler
Calidris maritima	purple sandpiper	*Phylloscopus inornatus*	yellow-browed warbler
Calidris mauri	western sandpiper	*Pinguinus impennis*	great auk
Calidris melanotos	pectoral sandpiper	*Plectrophenax nivalis*	snow bunting
Calidris minuta	little stint	*Pluvialis dominica*	lesser golden plover
Calidris ruficollis	red-necked stint	*Pluvialis fulva*	Pacific golden plover
Calidris tenuirostris	great knot	*Pluvialis squatarola*	black-bellied plover
Carduelis chloris	greenfinch	*Polysticta stelleri*	Steller's eider
Carduelis hornemanni	Arctic redpoll	*Puffinus gravis*	greater shearwater
Catharacta skua	great skua	*Puffinus griseus*	sooty shearwater
Cepphus columba	pigeon guillemot	*Rhodostethia rosea*	Ross' gull
Cepphus grylle	black guillemot	*Rissa brevirostris*	red-legged kittiwake
Charadrius semipalmatus	semipalmated plover	*Rissa tridactyla*	black-legged kittiwake
Chen caerulescens	lesser snow goose	*Somateria fisheri*	spectacled eider
Clangula hyemalis	long-tailed duck/ oldsquaw	*Somateria mollissima*	common eider
Corvus corax	raven/ common raven	*Somateria spectabilis*	king eider
Cygnus columbianus	tundra swan/ whistling swan	*Stercorarius longicaudus*	long-tailed jaeger
Emberiza pusilla	little bunting	*Stercorarius parasiticus*	Arctic skua/ parasitic jaeger
Eremophila alpestris	shore lark	*Sterna hirundo*	common tern
Eurynorhynchus pygmaeus	spoon-billed sandpiper	*Sterna paradisaea*	Arctic tern
Falco peregrinus	peregrine falcon	*Sula bassanus*	northern gannet
Falco rusticolus	gyrfalcon	*Synthliboramphus antiquus*	ancient murrelet
Fratercula arctica	Atlantic puffin	*Tetrao urogallus*	wood grouse
Fratercula cirrhata	tufted puffin	*Tetrastes bonasia*	hazel grouse
Fratercula corniculata	horned puffin	*Tringa erythropus*	spotted redshank

Tryngites subruficollis	buff-breasted sandpiper
Turdus iliacus	redwing
Turdus migratorius	American robin
Turdus pilaris	fieldfare
Uria aalge	common murre
Uria lomvia	Brünnich's guillemot/ thick billed murre
Vanellus vanellus	northern lapwing
Xema sabini	Sabine's gull

Fish

Abramis brama	carp bream
Alosa spp.	alewifes
Ammodytes americanus	sand lance
Ammodytes dubius	sand lance
Anarhichas lupus lupus	wolffish
Anguilla anguilla	eel
Arctogadus glacialis	Arctic cod
Atheresthes stomias	arrowtooth flounder
Berryteuthis magister magister	commander squid
Boreogadus saida	Arctic cod/ polar cod
Brosme brosme	tusk
Catostomus spp.	suckers
Cetorhinus maximus	basking shark
Chrosomus eos	northern redbelly dace
Clupea harengus	Atlantic herring
Clupea pallasi	Pacific herring
Coregonus albula	vendace
Coregonus artedi	lake cisco
Coregonus autumnalis	Arctic cisco
Coregonus clupeaformis	lake whitefish
Coregonus lavaretus	whitefish/ powan
Coregonus nasus	broad whitefish
Coregonus pidschian	Siberian whitefish
Coregonus sardinella	least cisco
Cottus spp.	sculpins
Cottus cognatus	slimy sculpin
Couesius plumbeus	lake chub
Dallia spp.	blackfishes
Dicentrachus labrax	sea bass
Eleginus gracilis	saffron cod
Engraulis mordax	northern anchovy
Esox lucius	northern pike
Gadus macrocephalus	Pacific cod
Gadus morhua	Atlantic cod
Gadus ogac	Greenland cod
Gasterosteus aculeatus	threespine stickleback
Glyptocephalus cynoglossus	witch
Gymnocephalus cernuus	ruffe
Haliotis rufuscens	abalone
Hemilepidotus jordani	yellow Irish lord
Hiodon alosoides	goldeye
Hippoglossoides elassodon	flathead sole
Hippoglossoides platessoides	long rough dab/ American plaice
Hippoglossoides robustus	northern flathead sole
Hippoglossus hippoglossus	halibut
Hippoglossus stenolepis	Pacific halibut
Hypomesus olidus	pond smelt
Icelus spiniger	thorny sculpin
Illex illecebrosus	squid
Lamna ditropis	salmon shark
Lepidopsetta bilineata	rock sole
Lepomis macrochirus	bluegill
Leuciscus idus	ide
Leuciscus leuciscus baicalensis	common dace
Limanda aspera	yellowfin sole
Lota lota	burbot
Mallotus villosus	capelin
Melanogrammus aeglefinus	haddock
Microgadus proximus	Pacific tomcod
Micromesistius poutassou	blue whiting
Micropterus dolomieu	smallmouth bass
Mola mola	ocean sunfish
Molva molva	ling
Myoxocephalus quadricornis	fourhorn sculpin
Noemacheilus barbatulus	stone loach
Notidanus griseus	bluntnose sixgill shark
Notropis atherinoides	emerald shiner
Oncorhynchus gorbuscha	pink salmon
Oncorhynchus keta	chum salmon
Oncorhynchus kisutch	coho salmon
Oncorhynchus mykiss	rainbow trout
Oncorhynchus nerka	sockeye salmon
Oncorhynchus tshawytscha	chinook salmon
Osmerus mordax	smelt/ rainbow smelt
Perca flavescens	yellow perch
Perca fluviatilis	European perch
Percopsis omiscomaycus	trout perch
Petromyzon marinus	lamprey
Pleurogrammus monoptergius	Atka mackerel
Pleuronectes asper	yellowfin sole
Pleuronectes bilineatus	rock sole
Pleuronectes ferrugineus	flounder
Pleuronectes glacialis	Arctic flounder
Pleuronectes platessa	plaice
Pleuronectes quadrituberculatus	Alaska plaice
Pollachius virens	coal fish/ saithe
Prosopium cylindraceum	round whitefish
Psetta maxima	turbot
Pungitius pungitius	ninespine stickleback
Reinhardtius hippoglossoides	Greenland halibut
Rutilus rutilus	roach
Salmo gairdneri	rainbow trout
Salmo salar	Atlantic salmon
Salmo trutta	brown trout
Salvelinus alpinus	Arctic char
Salvelinus confluentus	bull trout
Salvelinus fontinalis	brook trout
Salvelinus malma	Char/ Dolly Varden
Salvelinus namaycush	lake trout
Sander lucioperca	zander
Sander vitreus	walleye
Scomber japonicus	Pacific mackerel
Scomber scombrus	Atlantic mackerel
Scomberesox saurus	Atlantic saury
Sebastes marinus	redfish
Sebastes mentella	redfish
Sebastes viviparus	redfish
Squalus acanthias	spurdog
Stenodus leucichthys	inconnu
Thaleichthys pacificus	eulachon
Theragra chalcogramma	pollock
Thunnus thynnus	northern bluefin tuna
Thymallus arcticus	Arctic grayling
Trachurus trachurus	horse mackerel
Xiphias gladius	swordfish

Marine mammals

Balaena mysticetus	Greenland right whale/ bowhead whale
Balaenoptera acutorostrata	minke whale
Balaenoptera borealis	sei whale
Balaenoptera musculus	blue whale
Balaenoptera physalus	fin whale
Callorhinus ursinus	northern fur seal
Cystophora cristata	hooded seal
Delphinapterus leucas	beluga whale/ white whale
Enhydra lutris	sea otter
Erignathus barbatus	bearded seal
Eschrichtius robustus	grey whale
Eubalaena glacialis	right whales
Eubalaena japonica	North Pacific right whale
Eumetopias jubatus	Steller sea lion
Globicephala melaena	pilot whale
Halichoerus grypus	grey seal
Hydrodamalis gigas	Steller sea cow
Lagenorhynchus acutus	white-sided dolphin
Lagenorhynchus albirostris	white-beaked dolphin
Megaptera novaeangliae	humpback whale
Monodon monoceros	narwhal
Odobenus rosmarus	walrus
O. r. divergens	Pacific walrus
O. r. rosmarus	Atlantic wlarus
Orcinus orca	killer whale
Phoca fasciata	ribbon seal
Phoca groenlandica	harp seal
Phoca hispida	ringed seal
Phoca largha	spotted seal
Phoca vitulina	harbour seal
Phocoena phocoena	harbour porpoise
Phocoenoides dalli	Dall's porpoise/ Dahl's porpoise
Physeter catodon	sperm whale

Tursiops truncatus	bottlenose dolphin
Ursus maritimus	polar bear

Terrestrial mammals

Alces alces	moose
Alopex lagopus	Arctic fox
Bison bison	buffalo
Canis lupus	wolf
Castor canadensis	beaver
Cervus elaphus	red deer
Cervus nippon	Sika deer
Clethrionomys rufocanus	grey-sided vole
Clethrionomys rutilus	red-backed vole
Coelodonta antiquitatis	woolly rhinocerous
Dicrostonyx groenlandicus	collared lemming
Dicrostonyx torquatus	Arctic lemming
Erethizon dorsatum	porcupine
Gulo gulo	wolverine
Lemmus lemmus	Norway lemming
Lemmus sibiricus	brown lemming
Lepus americanus	snowshoe hare
Lepus arcticus	Arctic hare
Lepus timidus	hare/ mountain hare
Lynx lynx	lynx
Mammuthis primigenius	mammoth
Martes zibellina	sable
Megaloceros giganteus	giant deer/ Irish elk
Microtus abbreviatus	insular vole
Microtus gregalis	narrow-headed vole
Microtus middendorffi	Middendorf's vole
Microtus oeconomus	tundra vole
Microtus rossiaemeridionalis	sibling vole
Moschus moschiferus	musk deer
Mus musculus	house mouse
Mustela erminea	ermine
Mustela vison	mink
Mustela nivalis	least weasel
Odocoileus hemionus	mule deer
Ondatra zibethicus	muskrat
Ovibos moschatus	muskox
Ovis canadensis dalli	Dall sheep
Puma concolor	cougar
Rangifer tarandus	caribou/reindeer
R. t. pearyi	Peary caribou
Rattus norvegicus	Norway rat
Sorex spp.	shrews
Spermophilus parryii	ground squirrel
Tamiasciurus hudsonicus	red squirrel
Ursus arctos	grizzly bear/ brown bear
Ursus major	brown bear
Vulpes vulpes	red fox

Lower Animals

Acyrthosiphon spp.	aphids
Agrilus anxius	bronze birch borer
Alopecosa hirtipes	[spider]
Alvania	[gastropod]
Apherusa glacialis	[amphipod]
Asplanchna priodonta	[zooplankton]
Balanus balanoides	[barnacle]
Balanus balanus	[barnacle]
Bombus balteatus	[bumblebee]
Bombus cingulatus	[bumblebee]
Bombus hyperboreus	[bumblebee]
Bombus polaris	[bumblebee]
Bosmina longirostris	[zooplankton]
Calanus finmarchicus	[zooplankton]
Calanus hyperboreus	[zooplankton]
Calanus glacialis	[zooplankton]
Calanus marshallae	[zooplankton]
Calliopidae	[amphipod]
Cancer magister	Dungeness crab
Carabus truncaticollis	[ground beetle]
Ceriodaphnia quadrangula	[water flea]
Chaetozone setosa	[polychaete]
Chiloxanthus pilosus	[mite]
Chionoecetes bairdi	Tanner crab
Chionoecetes opilio	snow crab
Chlamys islandica	Iceland scallop

Chone paucibranchiata	[polychaete]
Choristoneura fumiferana	eastern spruce budworm
Choristoneura pinus pinus	jack pine budworm
Chrysaora melamaster	[jellyfish]
Clossiana sp.	fritillary butterfly
Cotesia jucunda	[parasitic wasp]
Curtonotus alpinus	[ground beetle]
Cyclops scutifer	[cladoceran]
Danaus plexippus	milkweed butterfly
Daphnia longiremis	[cladoceran]
Daphnia middendorffiana	[cladoceran]
Daphnia pulex	[cladoceran]
Daphnia pulicaria	[cladoceran]
Daphnia umbra	[cladoceran]
Dendroctonus rufipennis	spruce bark beetle
Dendrolimus sibiricus	Siberian silkworm
Dioryctria reniculelloides	spruce coneworm
Dreissena polymorpha	zebra mussel
Epirrita autumnata	autumnal moth
Eucalanus bungii	[zooplankton]
Euphausia pacifica	[krill]
Folsomia quadrioculata	[collembolan]
Folsomia regularis	[collembolan]
Folsomia sexoculata	[collembolan]
Gammarus lacustris	freshwater shrimp
Gammarus oceanicus	[amphipod]
Gammarus setosus	[amphipod]
Gammarus wilkitzkii	[amphipod]
Gorgonocephalus caputmedusae	[brittle star]
Gynaephora groenlandica	[moth]
Harpinia spp.	amphipods
Heterocope spp.	copepods
Hiatella arctica	[bivalve]
Hormathia nodosa	[actinarian]
Hypogastrura tullbergi	[collembolan]
Hypogastrura viatica	[collembolan]
Ips typographus	spruce engraver beetle
Janira maculosa	[isopod]
Lepidurus	[benthic invertebrate]
Limacina helicina	[pteropod]
Lithodes aequispina	[crab]
Littorina saxatilis	[gastropod]
Lymantria dispar	gypsy moth
Lymnaea elodes	[snail]
Macoma spp.	clams
Malacosoma disstria	forest tent caterpillar
Maldane sarsi	[polychaete]
Metridia longa	[zooplankton]
Metridia pacifica	[zooplankton]
Munna	[isopod]
Mya arenaria	[clam]
Mya truncata	[clam]
Mysis relicta	opossum shrimp
Mytilus edulis	blue mussel
Neocalanus spp.	zooplankton
Neodiprion sertifer	European pine sawfly
Onisimus spp.	amphipods
Onychiurus arcticus	[collembolan]
Onychiurus groenlandicus	[collembolan]
Operophtera brumata	winter moth
Ophiopholis aculeata	[isopod]
Pandalopsis dispar	deepwater prawn
Pandalus borealis	deepwater prawn/ deepwater shrimp/ northern shrimp
Pandalus goniurus	humpy shrimp
Pandalus jordani	pandalid shrimp
Paragorgia arborea	red gorgonian
Paralithodes camtschatica	red king crab
Paralithodes camtschaticus	king crab
Parasyrphus tarsatus	[flower-fly]
Phyllocnistis populiella	aspen leaf miner
Pristiphora erichsonii	larch sawfly
Pterostichus costatus	[ground beetle]
Rana sylvatica	wood frog
Rana temporaria	common frog
Scoloplos armiger	[polychaete]
Spio filicornis	[polychaete]
Spiochaetopterus typicus	[polychaete]
Themisto libellula	[amphipod]
Thyasira	[bivalve]
Thysanoessa inermis	[krill]

Thysanoessa longicauda	[krill]
Thysanoessa longipes	[krill]
Thysanoessa raschii	[krill]
Tipula carinifrons	[crane fly]
Tonicella	[barnacle]
Umingmakstrongylus pallikuukensis	muskox lungworm
Urticina eques	[actinarian]
Vertagopus brevicaudus	[collembolan]

Higher plants

Abies spp.	firs
Abies sibirica	Siberian fir
Allium schoenoprasum	wild chive
Alnus spp.	alders
Alnus fruticosa	alder
Alopecurus alpinus	alpine foxtail
Andromeda polifolia	bog rosemary
Arctophila fulva	pendant grass
Artemisia spp.	sagebrushes
Betula ermanii	gold birch
Betula exilis	dwarf birch
Betula nana	dwarf birch
Betula papyrifera	paper birch
Betula pendula	silver birch
Betula pubescens	downy birch
B. p. czerepanovii	mountain birch
Calamagrostis lapponica	Lapland reedgrass
Calluna vulgaris	heather
Cardamine pratensis	cuckoo flower
Carex aquatilis	water sedge
Carex bigelowii	Bigelow's sedge
Carex bigelowii / arctisibirica	[sedge]
Carex chordorrhiza	creeping sedge
Carex duriuscula	needleleaf sedge
Carex ensifolia	[sedge]
Carex lugens	[sedge]
Carex stans	water sedge
Carex subspathacea	Hoppner's sedge
Carpinus spp.	hornbeams
Cassiope tetragona	white arctic mountain heather
Cerastium beeringianum	Bering chickweed
Cerastium regelii	Regel's chickweed
Chrysosplenium alternifolium	alternate-leaved golden-saxifrage
Corallorrhiza spp.	coralroots
Cortusa matthioli	bear's ear sanicle
Draba oblongata	Canadian arctic draba
Draba subcapitata	Ellesmereland whitlowgrass
Dryas integrifolia	Arctic dryad
Dryas octopetala / punctata	mountain avens
Dupontia fisheri	Fisher's tundra grass
Dupontia psilosantha	Fisher's tundra grass
Empetrum hermaphroditum	mountain crowberry
Empetrum nigrum	crowberry
Equisetum spp.	horsetails
Eriophorum angustifolium	tall cottongrass
Eriophorum scheuchzeri	white cottongrass
Eriophorum vaginatum	cottongrass
Eritrichium nanum	alpine cushion plant
Euphrasia frigida	cold eyebright
Fagus sylvatica	beech
Galium densiflorum	[herb]
Gentiana nivalis	snow gentian
Geum spp.	avens
Helictotrichon krylovii	[herb]
Juniperus communis	creeping juniper
Kobresia spp.	bog sedges
Koenigia islandica	Iceland purslane
Lagotis minor	little weaselsnout
Larix cajanderi	Cajander larch
Larix dahurica	Dahurian larch
Larix gmelinii	Gmelin larch
Larix laricina	tamarack
Larix sibirica	Siberian larch
Larix sukaczewii	Sukachev larch
Ledum spp.	Labrador teas
Lemna spp.	duckweeds
Lupinus spp.	lupines
Luzula confusa	northern woodrush
Menyanthes spp.	bogbeans
Oxycoccus spp.	cranberries

Oxyria digyna	Arctic sorrel
Papaver polare	Arctic poppy
Pedicularis hirsuta	hairy lousewort
Phippsia algida	ice grass
Phleum alpinum	alpine timothy
Picea abies	Norway spruce
Picea glauca	white spruce
Picea mariana	black spruce
Picea obovata	Siberian spruce
Picea sitchensis	Sitka spruce
Pinus contorta	lodgepole pine
Pinus pumila	Dwarf Siberian pine
Pinus sibirica	Siberian stone pine
Pinus sylvestris	Scots pine
Poa abbreviata	northern bluegrass
Polygonum amphibium	water smartweed
Polygonum viviparum	alpine bistort
Populus balsamifera	balsam poplar
Populus tremula	European aspen
Populus tremuloides	aspen
Populus trichocarpa	black cottonwood
Potamogeton spp.	pondweeds
Puccinellia phryganodes	creeping alkaligrass
Quercus spp.	oaks
Ranunculus glacialis	glacier buttercup
Ranunculus sabinei	Sardinian buttercup
Rhododendron spp.	rhododendrons
Rubus chamaemorus	cloudberry
Salix arctica	arctic willow
Salix glauca	glaucous willow
Salix herbacea	dwarf willow
Salix lanata	hairy willow
Salix myrsinifolia	dark-leaved willow
Salix myrsinites	whortle-leaved willow
Salix myrtilloides	[willow]
Salix phylicifolia	tea-leaved willow
Salix polaris	polar willow
Salix pulchra	tealeaf willow
Salix reptans	[willow]
Sanguisorba officinalis	official burnet
Saxifraga caespitosa	tufted alpine saxifrage
Saxifraga cernua	nodding saxifrage
Saxifraga hyperborea	pygmy saxifrage
Saxifraga nivalis	alpine saxifrage
Saxifraga oppositifolia	purple saxifrage
Silene acaulis	moss campion
Sorbus aucuparia	rowan
Taraxacum officinale	dandelion
Tilia spp.	lindens
Vaccinium myrtillus	blueberry/ bilberry
Vaccinium uliginosum	bog blueberry/ bog whortleberry/ bog bilberry
Vaccinium vitis-idaea	lingonberry

Lower plants

Achnanthes	[diatom]
Ahnfeltia plicata	[red algae
Alaria esculenta	[kelp]
Arctocetraria nigricascens	[lichen]
Aulacomnium turgidum	[moss]
Bryum cyclophyllum	[moss]
Cetraria islandica	[lichen]
Cetrariella delisei	[lichen]
Cinclidium arcticum	[moss]
Cladina	[lichen]
Cladina rangiferina	[lichen]
Cladonia	[lichen]
Cladonia arbuscula	[lichen]
C. a. mitis	[lichen]
Cladonia pyxidata	[lichen]
Cladonia uncialis	[lichen]
Climacium dendroides	[forest moss]
Cyclotella	[diatom]
Dactylina madreporiformis	[lichen]
Dactylina ramulosa	[lichen]
Dicranoweisia crispula	[moss]
Drepanocladus intermedius	[moss]
Fragilaria	[diatom]
Fucus distichus	sea-tangle (seaweed)
Hylocomium splendens	[moss]

Laminaria digitata	[kelp]
Laminaria saccharina	[kelp]
Laminaria solidungula	[kelp]
Orthothecium chryseon	[moss]
Phaeocystis pouchetii	[flagellate]
Pleurozium shreberi	[forest moss]
Pogonatum alpinum	[bryophyte]
Polytrichum commune	[moss]
Polytrichum juniperinum	[moss]
Psora decipiens	[lichen]
Ptilidium ciliare	[liverwort]
Racomitrium lanuginosum	[moss]
Rhizoplaca melanophthalma	[lichen]
Rhytidiadelphus triquetrus	[forest moss]
Seligeria polaris	[moss]
Sphagnum fuscum	[moss]
Stereocaulon paschale	[lichen]
Thamnolia subuliformis	[lichen]
Tomentypnum nitens	[moss]
Tortula ruralis	[moss]
Xanthoria candelaria	[lichen]
Xanthoria parietina	[lichen]

Misc. fungi/bacteria etc.

Alternaria	[fungus]
Archaeoglobus	[bacterium]
Archaeoglobus fulgidus	[bacterium]
Arthrobacter	[bacterium]
Aspergillus	[fungus]
Azotobacter	[bacterium]
Bacillus	[bacterium]
Beijerinckia indica	[bacterium]
Botrytis	[fungus]
Clostridium	[bacterium]
Cortinarius	[fungus]
Cryptococcus laurentii	[yeast]
Exobasidium	[fungus]
Fusarium	[fungus]
Inocybe	[fungus]
Metarhizium	[fungus]
Metarhizium anisopliae	[fungus]
Methylocapsa	[bacterium]
Methylocella	[bacterium]
Microcoleus chthonoplastes	[cyanobacteria]
Mucor hiemalis	[fungus]
Nostoc spp.	[cyanobacteria]
Penicillium	[fungus]
Pseudomonas	[bacterium]
Pyrococcus	[bacterium]
Rhizopus	[fungus]
Thermococcus	[bacterium]
Truncatella truncata	[fungus]

Acronyms

ABL	Atmospheric boundary layer
ACIA	Arctic Climate Impact Assessment
ACD	Arctic Coastal Dynamics project
AEPS	Arctic Environmental Protection Strategy
AFI	Air freezing index
AGCM	Atmospheric general circulation model
AMAP	Arctic Monitoring and Assessment Programme
AO	Arctic Oscillation
AO$^-$	Low AO index
AO$^+$	High AO index
AOGCM	Atmosphere–ocean general circulation model
ARCMIP	Arctic Regional Climate Model Intercomparison Project
ATI	Air thawing index
AVHRR	Advanced Very High Resolution Radiometer
β-HCH	beta-Hexachlorocyclohexane
BOREAS	Boreal Ecosystem–Atmosphere Study
BP	Before present
C	Carbon
CAFF	Conservation of Arctic Flora and Fauna
CCSR	Center for Climate System Research (Japan)
Cd	Cadmium
CDOM	Colored dissolved organic matter
CDQ	Community Development Quota program (Alaska)
CFC	Chlorofluorocarbon
CGCM2	An AOGCM developed by the Canadian Centre for Climate Modelling and Analysis
CH$_4$	Methane
Chl-a	Chlorophyll-a
CMIP	Coupled Model Intercomparison Project
CO	Carbon monoxide
CO$_2$	Carbon dioxide
CPAN	Circumpolar Protected Area Network
CPUE	Catch-Per-Unit-Effort
CRU	Climatic Research Unit (University of East Anglia, UK)
CSM_1.4	An AOGCM developed by the National Center for Atmospheric Research (USA)
CTM	Chemical transport model
D-O	Dansgaard-Oeschger
DDT	Dichlorodiphenyltrichloroethane
DEWG	Denendeh Environmental Working Group
DIC	Dissolved inorganic carbon
DMS	Dimethyl sulfide
DO	Dissolved oxygen
DOC	Dissolved organic carbon
DU	Dobson unit
E	Evapotranspiration
ECHAM4/OPYC3	An AOGCM developed by the Max Planck Institute for Meteorology (Germany)
ECMWF	European Centre for Medium-range Weather Forecasts
EEZ	Exclusive economic zone
ENSO	El Niño–Southern Oscillation
FAO	United Nations Food and Agriculture Organization
fCO$_2$	Fugacity of CO$_2$
GCM	General circulation model
GDD	Growing degree-day
GDP	Gross domestic product
GEP	Gross ecosystem production
GFDL-R30_c	An AOGCM developed by the Geophysical Fluid Dynamics Laboratory (USA)
Gg	Gigagram (10^9 grams)
GHCN	Global Historical Climatology Network
GHG	Greenhouse gas
GPS	Global Positioning System
GWP	Global warming potential
H	Hydrogen
H$_2$	Molecular hydrogen

H$_2$S	Hydrogen sulfide
ha	Hectare
HadCM3	An AOGCM developed by the Hadley Centre for Climate Prediction and Research (UK)
HCB	Hexachlorobenzene
HCH	Hexachlorocyclohexane
Hg	Mercury
Hg^0	Elemental mercury
Hg^{2+}	Divalent mercury
IABP	International Arctic Buoy Programme
IASC	International Arctic Science Committee
IBA	Important Bird Area
IBP	International Biological Programme
ICC	Inuit Circumpolar Conference
ICES	International Council for the Exploration of the Sea
IGBP	International Geosphere–Biosphere Programme
IPA	International Permafrost Association
IPCC	Intergovernmental Panel on Climate Change
ITEX	International Tundra Experiment
ITQ	Individual Transferable Quota system
IUCN	World Conservation Union
IWC	International Whaling Commission
J	Joule
K	Potassium
Kg	Kilogram (10^3 grams)
LGM	Last glacial maximum
LIA	Little Ice Age
LPJ	Lund-Potsdam-Jena dynamic global vegetation model
MDE	Mercury depletion event
MeHg	Methyl mercury
MIP	Model intercomparison project
MPI	Max Planck Institute for Meteorology (Germany)
mwe	Meter water equivalent
MWP	Medieval Warm Period
My	Million years
N	Nitrogen
N$_2$O	Nitrous oxide
NADW	North Atlantic Deep Water
NAFO	Northwest Atlantic Fisheries Organization
NAMMCO	North Atlantic Marine Mammal Commission
NAO	North Atlantic Oscillation
NASA	National Aeronautics and Space Administration (US)
NCAR	National Center for Atmospheric Research (US)
NCARP	Northern Cod Adjustment and Recovery Program (Canada)
NCEP	National Centers for Environmental Prediction of NOAA
NDVI	Normalized Difference Vegetation Index
NEAFC	North East Atlantic Fisheries Commission
NEP	Net ecosystem production
NH$_3$	Ammonia
NH$_4$	Ammonium
NIES	National Institute for Environmental Studies (Japan)
nm	Nautical mile
NO$_3$	Nitrate
NOAA	National Oceanic and Atmospheric Administration (US)
NPP	Net primary production
NRL	Sámi Reindeer Herders Association of Norway
NSF	National Science Foundation (US)
NWT	Northwest Territories (Canada)
O	Oxygen
OUML	Ocean upper mixed layer
P	Phosphorus
P	Precipitation
PAH	Polycyclic aromatic hydrocarbon
PAR	Photosynthetically active radiation

Pb	Lead
PBDE	Polybrominated diphenyl ether
PCB	Polychlorinated biphenyl
PCN	Polychlorinated naphthalene
$p\mathrm{CO_2}$	Difference in partial pressure of CO_2 (e.g., across the air–sea interface)
PDO	Pacific Decadal Oscillation
P-E	Precipitation minus evapotranspiration
Pg	Petagrams (10^{15} grams)
POC	Particulate organic carbon
POP	Persistent organic pollutant
ppmv	Parts per million by volume
PSC	Polar stratospheric cloud
PUFA	Polyunsaturated fatty acid
R	Runoff
R_A	Respiration, autotrophic
R_E	Respiration, ecosystem
R_H	Respiration, heterotrophic
RAF	Radiation amplification factor
RAIPON	Russian Association of Indigenous Peoples of the North
RCM	Regional climate model
RCS	Regional (age) curve standardization
RIMS	Rapid Integrated Monitoring System
RIVM	National Institute for Public Health and the Environment model
RUV	Remote underwater vehicle
S	Salinity
SBUV	Solar backscatter ultraviolet
SHEBA	Surface Heat Budget of the Arctic Ocean
SLP	Sea-level pressure
SO	Sulfur monoxide
SO_2	Sulfur dioxide
SO_x	Sulfur oxide
SRES	Special Report on Emissions Scenarios (by the IPCC)
SST	Sea surface temperature
Sv	Sverdrup (unit = 10^6 m³/s)
SZA	Solar zenith angle
T	Tonne
TAC	Total allowable catch
TEK	Traditional ecological knowledge
Tg	Teragrams (10^{12} grams)
THC	Thermohaline circulation
TOMS	Total Ozone Mapping Spectrometer
TOPEX/ POSEIDON	joint French/US altimeter satellite
UIUC	University of Illinois at Urbana-Champaign (US)
ULAQ	Università degli studi dell'Aquila (Italy)
UNCED	United Nations Conference on Environment and Development
UNEP	United Nations Environment Programme
UV	Ultraviolet
UV-A	Ultraviolet-A radiation (315–400 nm)
UV-B	Ultraviolet-B radiation (280–315 nm)
W	Watt
WMO	World Meteorological Organization
WWF	World Wide Fund for Nature
Zn	Zinc
ΣDDT	Sum of DDT, DDD, and DDE (concentrations)
ΣPCBs	Sum of a number of individual polychlorinated (PCB) congeners

Glossary

Actinic flux
  Radiation incident at a point, determined by integrating the spectral irradiance over all directions of incident light (units = $W/m^2/nm$).

Action spectrum
  A sensitivity function that describes the relative effectiveness of energy at different wavelengths in determining a biological response.

Active layer
  The layer of ground that is subject to annual thawing and freezing in areas underlain by permafrost.

Adaptive ability or capacity
  The ability of an organism, an ecosystem, or a human system (community, culture, enterprise) to adapt to environmental change.

Albedo
  The fraction of solar radiation reflected by a surface or object, often expressed as a percentage. Snow covered surfaces have a high albedo; the albedo of soils ranges from high to low; vegetation covered surfaces and oceans have a low albedo. The earth's albedo varies mainly through varying cloudiness, snow, ice, leaf area, and land cover changes.

Allochthonous
  Exogenous; originating outside and transported into a given system or area.

Anadromous
  An adjective describing fish that exhibit migratory behavior between fresh and marine waters characterized by spawning (and in ice-covered arctic seas also by overwintering) in freshwater and summer feeding in marine water.

Aquaculture
  Breeding and rearing fish and shellfish, etc.

Aquifer
  A stratum of permeable rock that bears water. An unconfined aquifer is recharged directly by local rainfall, rivers, and lakes, and the rate of recharge will be influenced by the permeability of the overlying rocks and soils. A confined aquifer is characterized by an overlying bed that is impermeable and the local rainfall does not influence the aquifer.

Arctic
  [See chapter 1, section 1.1, paragraph 4]

Athalassic
  Used of waters or water bodies that have not had any connection to the sea in geologically recent times, all ions in solution are thus derived from the substratum or atmosphere.

Atmospheric boundary layer
  The bottom layer of the troposphere that is in contact with the surface of the earth. It is often turbulent and is capped by a statically stable layer of air or temperature inversion. The atmospheric boundary layer depth (i.e., the inversion height) is variable in time and space, ranging from tens of meters in strongly statically stable situations, to several kilometers in convective conditions over deserts.

Benthic
  Pertaining to the sea bed, river bed, or lake floor.

Biodiversity
  The numbers and relative abundances of different genes (genetic diversity), species, and ecosystems (communities) in a particular area.

Biogeochemical cycle
  The cyclical system through which a given chemical element is transferred between biotic and abiotic parts of the biosphere.

Biota
  All living organisms of an area; the flora and fauna considered as a unit.

Bloom
  A reproductive explosion of microscopic organisms in a lake, river, or ocean.

Catadromous
  An adjective describing fish which exhibit migratory behavior between fresh and marine waters that is characterized by spawning in marine waters and feeding and early rearing in freshwaters.

Climate
  Climate in a narrow sense is usually defined as the "average weather" or more rigorously as the statistical description in terms of the mean and variability of relevant quantities over a period of time ranging from months to thousands or millions of years. The classical period is 30 years as defined by the WMO. These relevant quantities are most often surface variables such as temperature, precipitation and wind. Climate in a wider sense is the state, including a statistical description, of the climate system.

Climate change
  Climate change refers to a statistically significant variation in either the mean state of the climate, or in its variability, persisting for an extended period (typically decades or longer).

Climate feedback
  An interaction between processes in the climate system, where the result of an initial process triggers a second process that in turn influences the initial one. A positive feedback intensifies the original process, and a negative feedback reduces it.

Climatological baseline
  A period of years representing the current climate, the latter being understood as a statistical description in terms of the mean and variability over the period. A baseline period should: be representative of the present-day or recent average climate in the region considered; be of sufficient duration to encompass a range of climatic variations; cover a period for which data on all major climatological variables are abundant, adequately distributed in space, and readily available; include data of sufficiently high quality for use in evaluating impacts; and be consistent or readily comparable with baseline climatologies used in other impact assessments.

Co-management
  A system for management of wildlife populations in which responsibility is shared between the users of the resource and government entities with legal authority for management of wildlife.

Conservation
  The protection of environmental values associated with natural systems through planned management of natural resources to assure their continued viability and availability for human appreciation and use by preventing overexploitation, and protection from destruction or neglect.

Conspecific
  Belonging to the same species.

Contaminant
  A substance that is not naturally present in the environment or is present in unnatural concentrations that can, in sufficient concentration, result in potential negative effects on the health of humans, other organisms, and ecosystems.

Continental shelf
  A shallow submarine plain of varying width forming a border to a continent and typically ending in a steep slope to the ocean abyss.

Cryosphere
  The component of the climate system consisting of all snow, ice, and permafrost on and beneath the surface of the earth and ocean.

Demersal
  Living at or near the bottom of a sea or lake but having the capacity for active swimming.

Diadromous
  Migrating between fresh water and seawater.

Dose
  Dose rate integrated over a time period of exposure (units = J/m^2 (effective)).

Dose rate
  Spectral irradiance weighted by a biological action spectrum (units = W/m^2 (effective)).

Ecosystem
  A system of interacting living organisms together with their physical environment. The boundaries of what could be called an ecosystem are somewhat arbitrary, depending on the focus of interest or study. Thus the extent of an ecosystem could range from very small spatial scales to, ultimately, the entire earth.

Ecosystem function
  Ecosystem function includes carbon and nutrient cycling, soil processes, controls of trace gas exchange processes, primary and secondary productivity, and water and energy balance.

Ecosystem services

Ecological processes or functions that have value to individuals or society.

Ecosystem structure

The spatial structure of an ecosystem, trophic interactions, and community composition in terms of biodiversity.

Ecotone

A zone of transition from one major plant community to another. For example, the forest–tundra ecotone in high northern latitudes is a zone of patchy and often stunted tree growth intermixed with areas of tundra.

Emissions scenario

A plausible representation of the future development of emissions of substances that are potentially radiatively active (e.g., greenhouse gases and aerosols), based on a coherent and internally consistent set of assumptions about driving forces (such as demographic and socio-economic development, technological change) and their key relationships.

ENSO

El Niño in its original sense is a warm water current that periodically flows along the coast of Ecuador and Peru, disrupting the local fishery. This oceanic event is associated with a fluctuation in the intertropical surface pressure pattern and circulation in the Indian and Pacific Oceans, called the Southern Oscillation. This coupled atmospheric–oceanic phenomenon is collectively known as El Niño–Southern Oscillation, or ENSO.

Environment

The complex of climatic, edaphic, and biotic factors that act upon an organism or an ecological community and ultimately determine its form and survival. From the human perspective, also inclusive of the aggregate of social and cultural conditions that influence the life of an individual or community.

Erythema

Reddening of the skin. Commonly called sunburn, it is most effectively caused by UV-B radiation.

Evapotranspiration

The combined process of evaporation (the process by which a liquid becomes a gas) and transpiration (loss of water vapor from an organism through a membrane or through pores).

Extant

Existing or living at the present time.

Extinction

The complete disappearance of an entire species.

Extirpation

The disappearance of a species from part of its range; local extinction.

Fast ice (or land-fast ice)

Fast ice (or land-fast ice) is immobilized for up to 10 months each year by coastal geometry or by grounded ice ridges (stamukhi).

Finite-difference model

A model based on finite-difference approximations – the differences between the values of a function at two discrete points are used to approximate the derivatives of the function. Same as grid-point model.

Flux adjustment

To avoid the problem of coupled atmosphere–ocean general circulation models drifting into some unrealistic climate state, adjustment terms can be applied to the atmosphere–ocean fluxes of heat and moisture (and sometimes the surface stresses resulting from the effect of the wind on the ocean surface) before these fluxes are imposed on the model ocean and atmosphere.

Food chain

A sequence of organisms on successive trophic levels within a community, through which energy is transferred by feeding; energy enters the food chain during fixation by primary producers (mainly green plants) and passes to herbivores (primary consumers) and then to carnivores (secondary and tertiary consumers).

Food web

The network of interconnected food chains of a community.

Freshet

A rush of freshwater from rain or melted snow.

Gas hydrates or methane hydrates

In the presence of high concentrations of certain gases in the water, at low temperatures and high pressures, gas hydrates can form (i.e., open-structured water ice hosting gases such as methane, carbon dioxide or hydrogen sulphide). When the gas trapped in the icy compound is methane, this is known as methane hydrate. Methane hydrate is by far the most common naturally occurring gas hydrate. Other gases, including larger hydrocarbons and carbon dioxide, also form hydrate compounds.

Giardiasis

An infection caused by the parasite *Giardia lamblia*.

Greenhouse gases

Greenhouse gases are those gaseous constituents of the atmosphere, both natural and anthropogenic, that absorb and emit radiation at specific wavelengths within the spectrum of infrared radiation emitted by the earth's surface, atmosphere, and clouds. This property causes the greenhouse effect. Water vapor, carbon dioxide, nitrous oxide, methane, and ozone are the primary greenhouse gases in the earth's atmosphere. A major proportion of these gases derive from past and present life processes on the earth, including decomposition of organic matter, respiration of plants and animals, burning of forests and other plant material, and burning of coal, oil, and other fossil fuels.

Halocline

A zone of marked salinity gradient.

Indigenous people

People whose ancestors inhabited a place or a country when persons from another culture or ethnic background arrived on the scene and dominated them through conquest, settlement, or other means and who today live in more conformity with their own social, economic, and cultural customs and traditions than those of the country of which they now form a part. Such people are often referred to in the Arctic as "aboriginal", "Native", "first nations", or "tribal".

Irradiance

Radiant power per unit area (units $= W/m^2$).

Native

Official legal term used in Alaska for indigenous people as a result of wording in the Alaska Native Claims Settlement Act of 1971.

Net ecosystem production

Net gain or loss of carbon from an ecosystem. Net ecosystem production is equal to the gross primary production (carbon fixed by plants through the process of photosynthesis) minus the carbon lost through heterotrophic respiration.

Net primary production

The increase in plant biomass or carbon of a unit of a landscape. Net primary production is equal to the gross primary production (carbon fixed by plants through the process of photosynthesis) minus carbon lost through autotrophic respiration.

Nival

Pertaining to snow.

North Atlantic Oscillation

The North Atlantic Oscillation consists of opposing variations of barometric pressure near Iceland and near the Azores. On average, a westerly current between the Icelandic low pressure area and the Azores high pressure area carries cyclones and their associated frontal systems towards Europe. However, the pressure difference between Iceland and the Azores fluctuates on timescales of days to decades, and can be reversed at times. It is the dominant mode of winter climate variability in the North Atlantic region, ranging from central North America to Europe.

Northeast Passage (Northern Sea Route)

The route of potential ship transit through the Arctic Ocean north of Eurasia between the Barents and Bering Seas.

Northwest Passage

The route of potential ship transit north of North America between the Labrador and Bering Seas.

Nunatak

A mountain peak or rocky outcrop projecting above an ice cap.

Ocean outfall

A discharge pipe used for the final disposal of wastewater extending from a wastewater treatment works to the point of discharge in marine waters.

Ontogenetic migration

The occupation by an animal of different habitats at different stages of development.

Ozone layer

The stratosphere contains a layer in which the concentration of ozone is greatest, the so-called ozone layer. The layer extends from about 12 to 40 km. The ozone concentration reaches a maximum between 20 and 25 km. This layer is being depleted by human emissions of chlorine and bromine compounds. These compounds interact photochemically with the ozone to allow increased ultraviolet-B radiation to reach the earth's surface.

Pack ice

Ice formed on oceanic surfaces in polar regions, often encompassing ice bergs derived from calving of glaciers as glaciers enter the sea from land.

Paludification

The process of bog expansion.

Parameterization

In climate models, this term refers to the technique of representing processes that cannot be explicitly resolved at the spatial or temporal resolution of the model (sub-grid scale processes) by relation-

ships between the area- or time-averaged effect of such sub-grid-scale processes and the larger scale flow.

Pathogen

A microbiological agent capable of causing disease.

Pelagic

Pertaining to the water column of the sea or lake; used of organisms inhabiting the open waters of an ocean or lake.

Permafrost

Ground (soil or rock and included ice and organic material) that remains at or below 0 ºC for at least two consecutive years.

Phenology

The study of seasonal changes in plant and animal life and the relationships of these changes to weather and climate.

Phenotypic responses

Changes in the physical expression of a characteristic of an organism when experiencing a change in the environment and without genetic change.

Photokeratitis

Sunburn of the cornea resulting from overexposure to UV-B radiation that is usually reversible. It can occur after long periods on the snow, especially on bright, clear, sunny days, without adequate eye protection. It can be very painful for a couple of days and can result in transitory loss of vision.

Photoperiod

The relative lengths of seasonally alternating periods of lightness and darkness in the 24 hour day that affect the growth, activity, and reproductive timing in organisms.

Phytoplankton

The plant forms of plankton. Phytoplankton are the dominant plants in the sea, and are the basis of the entire marine food web. These single-celled organisms are the principal agents for photosynthetic carbon fixation in the ocean.

Piscivorous

Feeding on fish.

Pit privy (outhouse)

A structure that receives urine and excrement that is not water-borne; and is the final disposal site and not a temporary storage facility.

Planktivorous

Feeding on planktonic organisms.

Polar stratospheric clouds

Clouds that form at extremely low temperatures (below 195 K) in the stratosphere, mostly in the polar regions, and play a role in ozone depletion chemistry.

Polynya

A Russian term meaning an area of open water, possibly containing some thin ice, within the ice pack. A polynya is distinguished from a lead by being a broad opening rather than a long, narrow fracture.

Post and pad foundation

A building foundation system constructed with posts for vertical support and pads on the ground to distribute the load of each vertical support.

Prognostic variable

A variable that is described by an equation that contains a time derivative of this variable (a differential equation), and therefore its value can be determined at a later time when the other terms in the equation are known.

Proxy climate data

A proxy climate indicator is a local record that is interpreted, using physical and biophysical principles, to represent some combination of climate-related variations back in time. Climate-related data derived in this way are referred to as proxy data. Examples of proxies are tree ring records and various data derived from ice cores.

Quasi-biennial oscillation

An oscillation in the zonal winds of the equatorial stratosphere having a period that fluctuates between about 24 and 30 months. This oscillation is a manifestation of a downward propagation of winds with alternating sign. This phenomenon is sometimes referred to as the stratospheric quasi-biennial oscillation to distinguish it from other atmospheric features that also have spectral peaks near two years.

Refugium

An area that has escaped major climatic changes typical of a region as a whole and acts as a refuge for biota previously more widely distributed; an isolated habitat that retains the environmental conditions that were once widespread.

Regime shift

A rapid change in regional climate.

Resilience

Synonymous with "adaptive ability", or the ability of a system to undergo change without changing its state or identity.

Ruderal

Inhabiting disturbed sites.

Runoff

The water from rain or melted snow that travels over the ground surface.

Saline wedge

A salt-water layer flowing below a lower density freshwater layer that tends to form the shape of a wedge as it intrudes into a river system.

Species adaptation

Characteristics of an organism that have been selected by specific selection pressures exerted by other organisms or the physical environment and that have lead to a new genetic constitution.

Spectral irradiance

Radiant power per unit area (units $= W/m^2/nm$).

Spectral model

A model in which the prognostic field variables are represented as sums of a finite set of spectral modes rather than being given at grid points. The spectral modes may be Fourier modes in the one-dimensional case or double Fourier modes or spherical harmonics in the two-dimensional case. One advantage of a spectral model is that horizontal derivatives can be calculated exactly for the spectral modes represented in the model. Spectral models are, in general, computationally more efficient than a grid-point model with an equivalent resolution.

Stamukhi zone

The zone of heavily broken ice which marks the contact between land-fast ice and the moving pack-ice zones.

Stenothermal

A tolerance of a narrow range of environmental temperatures.

Storm surge

A temporary increase, at a particular locality, in the height of the sea due to extreme meteorological conditions (low atmospheric pressure and/or strong winds). The storm surge is defined as being the excess above the level expected from the tidal variation alone at that time and place.

Subpermafrost

Located beneath the permafrost.

Subsistence activity

An aspect of human existence involving derivation of food and other needs directly from the locally available natural resources.

Sustainability

The ability of a natural system (e.g., ecosystem, plant community, population of organisms) or a human-generated system (e.g., community, economy, culture) to maintain itself over time. Often used in reference to the ability of a renewable natural resource to yield a stable annual harvest over time.

Taiga

Russian term for the boreal or northern coniferous forest biome; the ecosystem adjacent to the arctic tundra.

Talik

A layer or body of unfrozen ground occurring in a permafrost area due to a local anomaly in thermal, hydrological, hydrogeological, or hydrochemical conditions.

Thermocline

A boundary region in water bodies (lakes or oceans) between two layers of water of different temperature, in which temperature changes sharply with depth.

Thermohaline circulation

Large-scale density-driven circulation in the ocean, caused by differences in temperature and salinity. In the north Atlantic, the thermohaline circulation consists of warm surface water flowing northward and cold deepwater flowing southward, resulting in a net poleward transport of heat. The surface water sinks in highly restricted sinking regions located in high latitudes.

Thermokarst

Irregular, hummocky topography in frozen ground caused by melting of ice.

Traditional knowledge

The accumulated knowledge of indigenous peoples about the environment in which they live that has been passed on via the elders of a community.

Trophic levels

The sequence of steps in a food chain; from producer to primary, secondary, or tertiary consumer.

Tundra

A type of ecosystem dominated by lichens, mosses, grasses, and dwarf woody plants. Tundra is found at high latitudes (arctic tundra) and high altitudes (alpine tundra). Arctic tundra is underlain by permafrost and is usually saturated.

Urocanic acid

A photoreceptor for the induction of UV immune suppression.

UV-A

The longest UV wavelengths (315–400 nm). Atmospheric gases absorb little UV-A radiation, so most reaches the earth's surface.

UV-B

Solar radiation within a wavelength range of 280–315 nm, the greater part of which is absorbed by stratospheric ozone. Enhanced UV-B radiation suppresses the immune system and can have other adverse effects on living organisms.

UV-C

The shortest UV wavelengths (100–280 nm). UV-C radiation is almost entirely absorbed by atmospheric oxygen and ozone.

UV index

A number reflecting the daily risk of overexposure (sunburning) to sunlight. Measured on a scale of 0 to >10, where 0 indicates minimal exposure and >10 indicates high to very high risk.

UV-induced immune suppression

A change in cell-mediated immunity induced by UV-B radiation. The result of UV-induced immune suppression is the production of regulatory T-cells (suppressor cells) as opposed to effector (antigen-attacking) T-cells.

Varve

A layer of sediment deposited in a lake during the course of a single year.

Vernal

Pertaining to the spring.

Wastewater

Waterborne human wastes or graywater derived from dwellings, commercial buildings, institutions, or similar structures; "wastewater" includes the contents of individual removable containers used to collect and temporarily store human wastes.

Weather

State of the atmosphere with regard to temperature, precipitation, wind, and degree of cloud cover.

Zooplankton

The animal forms of plankton. They consume phytoplankton or other zooplankton.

δ^{18}O

An expression for the ratio of the ^{18}O to ^{16}O atoms (stable isotopes of oxygen) in a sample relative to a standard, used as an indicator of temperature change over time, and defined as: δ^{18}O = (^{18}O/^{16}O sample - ^{18}O/^{18}O standard)/(^{18}O/^{16}O standard).

Earth's climate is changing, with the global temperature now rising at a rate unprecedented in the experience of modern human society. These climate changes, including increases in ultraviolet radiation, are being experienced particularly intensely in the Arctic. Because the Arctic plays a special role in global climate, these changes in the Arctic will also affect the rest of the world. It is thus essential that decision makers have the latest and best information available regarding ongoing changes in the Arctic and their global implications.

The Arctic Council called for this assessment and charged two of its working groups, the Arctic Monitoring and Assessment Programme (AMAP) and the Conservation of Arctic Flora and Fauna (CAFF), along with the International Arctic Science Committee (IASC), with its implementation. An Assessment Steering Committee was charged with the responsibility for scientific oversight and coordination of all work related to the preparation of the assessment reports.

This assessment was prepared over the past five years by an international team of over 300 scientists, other experts, and knowledgeable members of the indigenous communities. The report has been thoroughly researched, is fully referenced, and provides the first comprehensive evaluation of arctic climate change, changes in ultraviolet radiation, and their impacts for the region and for the world.

The scientific results reported herein provided the scientific foundation for the Arctic Climate Impact Assessment (ACIA) synthesis report, entitled "Impacts of a Warming Arctic", released in November 2004.
